## SUMMARY

The DOE Fuel Cycle Research & Development (FCR&D) Program is developing aqueous and electrochemical approaches to the processing of used nuclear fuel that will generate technetium-bearing waste streams. This report presents Pacific Northwest National Laboratory (PNNL) research to evaluate an iron-based alloy waste form for Tc that provides high waste loading within waste form processing limitations, meets waste form performance requirements for durability and the long-term retention of radionuclides, and can be produced with consistent physical, chemical, and radiological properties that meet regulatory acceptance requirements for disposal.

Microanalysis with scanning electron microscopy (SEM) was used to analyze a non-radioactive FeMo-Re sample. The Transmission Electron Microscope (TEM) was not functional and, therefore, only preliminary SEM work can be reported. The results are in agreement with previous studies (Ebert et al., 2009 and Frank et al., 2009).

# Technetium Waste Form Development – Progress Report

## 1. INTRODUCTION

Recycling of used nuclear fuel offers some significant advantages over direct disposal, yet the environmental issues associated with the waste forms created are unlikely to disappear. While these advanced waste forms may occupy considerably smaller volumes than previously developed waste forms, a repository may still be required for their ultimate disposal, whether this be in the form of long-term geological repository or a monitored storage facility. The behavior of the advanced waste forms need to be evaluated in terms of the full range of environmental conditions that are possible within a repository setting. Changes in environmental conditions are expected, and may originate from the waste forms themselves (e.g., heat, radiation damage, waste form corrosion), or may reflect the natural variability of the repository setting (e.g., water seepage rates, mechanical stability). In some cases, the environmental setting may directly reflect the durability of the waste form itself. It is important to have a good understanding of the microstructure of the waste forms to develop effective long-term models for corrosion and to build scientific basis for the disposal strategy.

Metallic waste forms were previously developed by Idaho National Laboratory (INL) for EBR-II wastes (Abraham et al., 2001). The minimum additive waste stabilization (MAWS) approach is being utilized to produce a metal waste form that both addresses the performance acceptance requirements and minimizes the amount of additional materials that needs to be added to make a durable material. In this project, a 48wt% Fe, 38 wt% Mo, with 14 wt% Re alloy (termed FeMo-Re alloy) and a 52 wt% Fe, 41 wt% Mo with 7 wt% Tc (termed FeMo-Tc alloy) were prepared at INL. Both samples were received at PNNL for further analyses with electron microscopy. Unlike the metals examined in the last campaign reported in Gelles et al. (2009), these materials did not contain zirconium.

Figure 1.1 Photograph of 48Fe-38Mo-14Re (FeMo-Re alloy). The diameter of the ingot was about 2 cm [image taken from Frank et al., 2009].

Initial XRD and SEM analyses at INL indicated both materials were multi-phase alloys. The XRD revealed differences between the FeMo-Re alloy and the FeMo-Tc alloy. Un-dissolved molybdenum was observed in the FeMo-Re alloy. The effects of processing time and heat treatments on the microstructure and phase compositions need to be determined as part of the metal waste form alloy development. In this study, only the FeMo-Re alloy was analyzed and only the SEM analyses are reported as the TEM was available owing to system failures.

As was found during analyses reported by Frank and co-workers (Frank et al., 2009), three phases were detected: An almost pure molybdenum phase which was thought to be residual metallic molybdenum wire that did not completely dissolve; an iron-rich phase, and a rhenium-rich iron phase. The appropriate phase diagrams (Frank et al., 2009) suggest that the rhenium-rich phase and  $\alpha$ -Fe (ferrite) phase with molybdenum will be stable between 1488 °C and 1200 °C. As the alloy cooled below 1200 °C, solid state diffusion may have been too slow to convert the rhenium-rich phase to another form that is thermodynamically more stable than the rhenium phase at lower temperatures and has slightly lower molybdenum content. The lever rule predicts the rhenium-rich phase should be present in greater abundance than the ferrite solid solution. These

predictions are borne out in the characterization studies reported here and elsewhere (Ebert et al., 2009).

## 2. RESULTS

### 2.1 Scanning Electron Microscopy of the FeMo-Re alloy

Several images and elemental maps were obtained together with x-ray energy dispersive spectroscopy (EDS) analyses of the FeMo-Re alloy. Elemental maps were also obtained that show the nature of the alloy phase. The magnification scale was checked against a standard (see Appendix A).

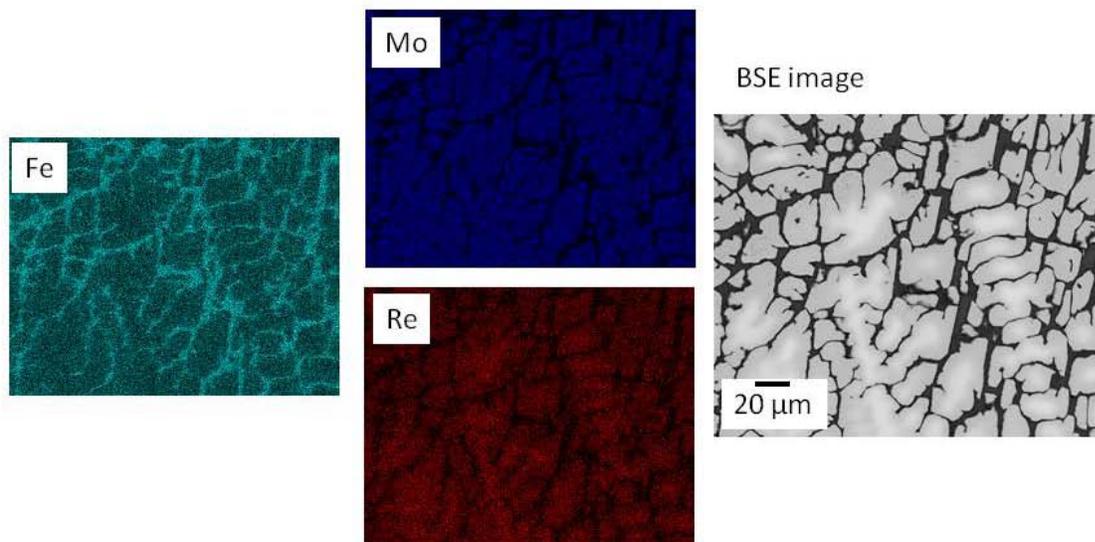

Figure 2.1 SEM analysis of FeMo-Re alloy; (a) iron map, (b) molybdenum map, (c) rhenium map, and (d) backscattered electron image.

The Fe-Re phase diagram suggests that an intermetallic phase ( $\eta$ ) will form initially and will equilibrate (and dissolve into) first with  $\delta$ -Fe and then remain dissolved in the  $\gamma$ -Fe that forms to replace the  $\delta$ -Fe (Ebert et al., 2009). Instead of forming the  $\eta$ -Fe-Re intermetallic phase, the rhenium appears to substitute into a FeMo intermetallic phase. In Figures 2.1 and 2.2, the SEM

images and elemental maps show the presence of these phases. There is a need to determine the nature of the iron phases but this cannot be determined without the structural analysis capabilities of TEM.

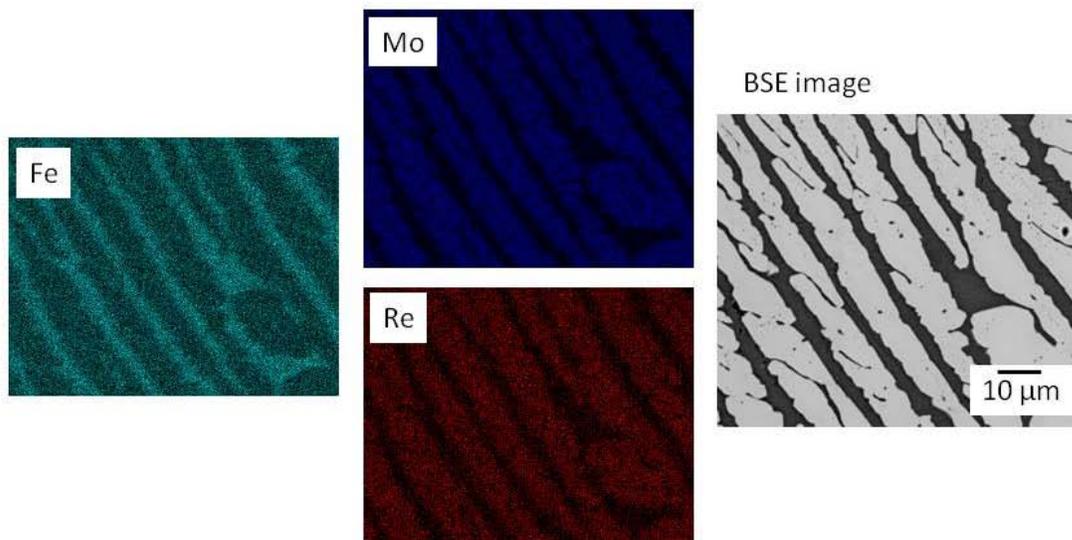

Figure 2.2 SEM analysis of FeMo-Re alloy; (a) iron map, (b) molybdenum map, (c) rhenium map, and (d) backscattered electron image.

In Figure 2.3, a concentrated region of molybdenum metal is shown. This feature was uncommon in the material and may be due to un-dissolved molybdenum wire as suggested by Frank et al. (2009). Adjacent to this molybdenum region, the rhenium was higher in concentration relative to iron.

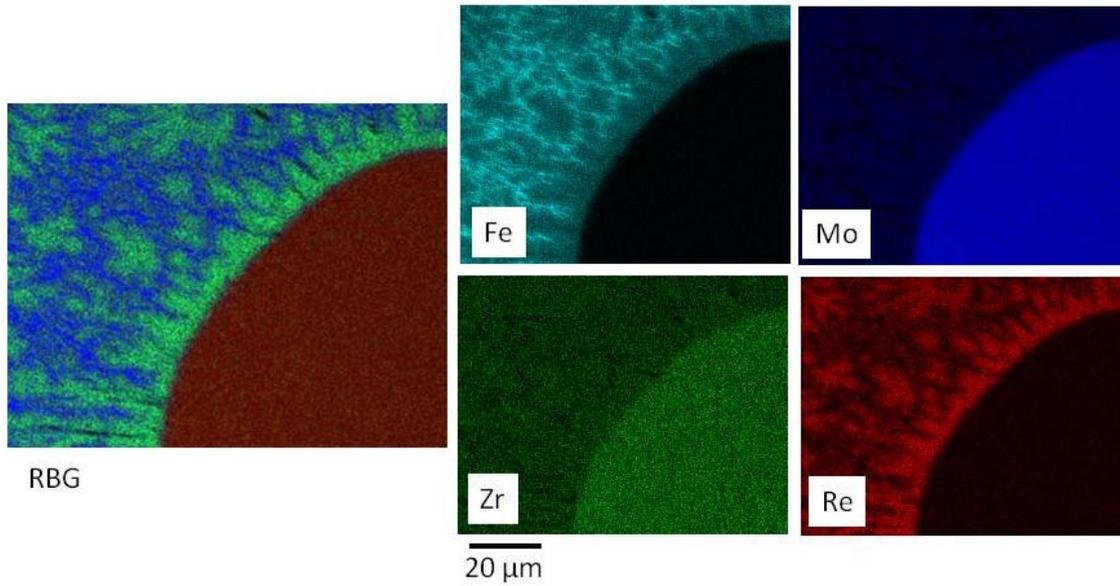

Figure 2.3 SEM analysis of FeMo-Re alloy; The RGB combination map used a mixture of elemental maps; iron, rhenium, and molybdenum. The instrument generated a map with Zr although Zr is not present in the alloy.

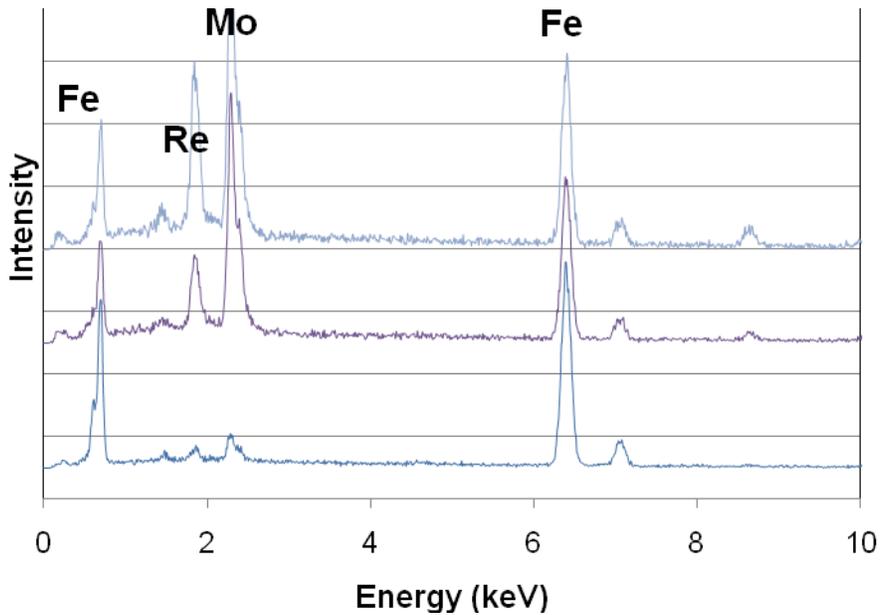

Figure 2.4 EDS of different phase compositions in the FeMo-Re alloy.

In Figure 2.4, EDS analyses from three different neighboring regions in the alloy are shown normalized to the iron Fe-K signal. The lower curve shows the ferrite composition, and the upper two spectra show two distinct compositions.

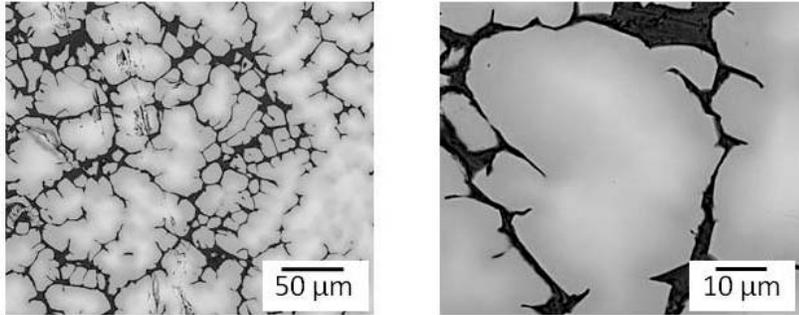

Figure 2.5 Backscattered images of FeMo-Re alloy showing a higher average Z material in the center of the Mo-Re rich regions.

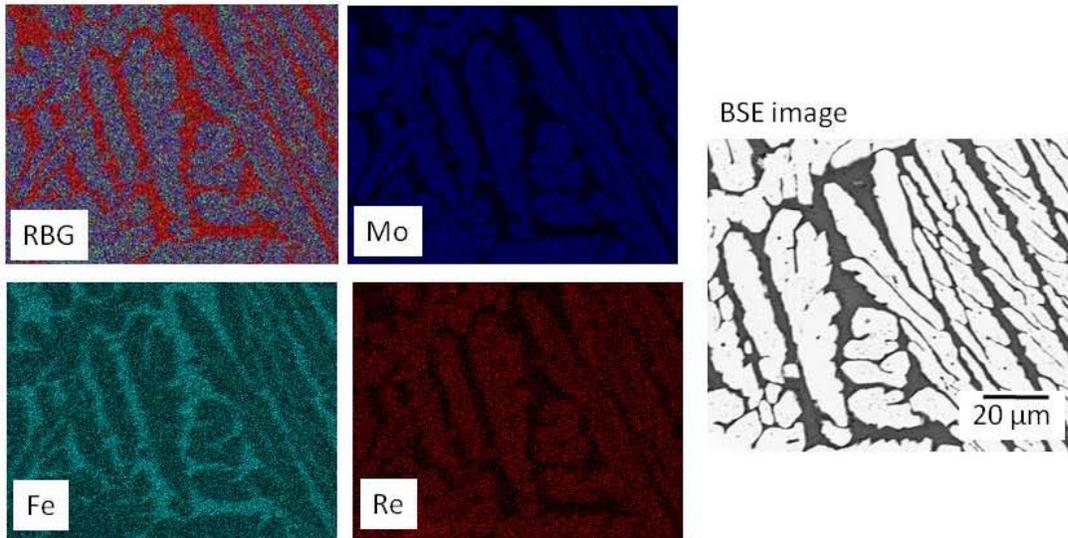

Figure 2.6 SEM analysis of FeMo-Re alloy, including a combination map, iron map, molybdenum map, rhenium map, and backscattered electron (BSE) image.

Backscattered images in Figure 2.5 of the metal waste form also reveal three phases, excluding the pure molybdenum phase. This additional rhenium-rich phase is only visible when the high Z

regions contrast is highlighted with BSE imaging. In the backscattered image in Figure 2.6, no significant contrast variation was observable and the rhenium rich region is not visible. In Figure 2.7, a series of spot analyses across the eutectic region show the variability in rhenium content but the presence of the third rhenium-rich phase is not as clear as in the backscattered images. Further work with TEM is required to determine if this is a separate phase or a solid solution. In Appendix B, relevant metal phases were selected and simulated electron diffraction patterns were generated.

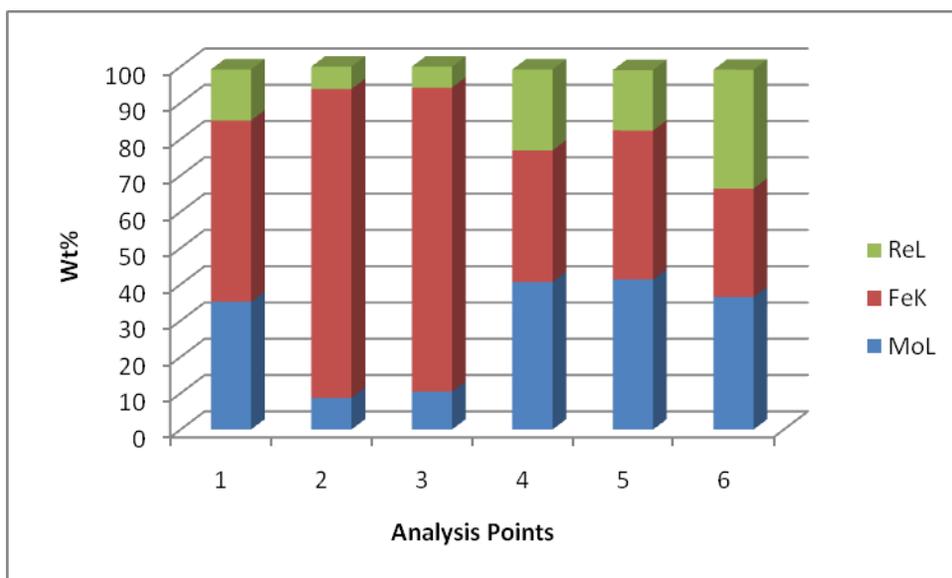

Figure 2.7 Series of data analyses showing variation in iron content.

## 2.2 TEM sample preparation

To produce samples suitable for TEM with radioactive materials, it is important to reduce the size of the samples as much as possible. An example of a TEM sample that was thinned using the tripod polisher technique is shown in Figure 2.7. These very small fragments were glued to a 3-mm diameter copper support ring for insertion into the TEM vacuum system. During polishing, it was clear that the softer iron (ferrite) is removed much more quickly than the intermetallic phases. As a result the material tends to fracture along the ferrite regions. Thus extreme care is required to produce electron transparent regions.

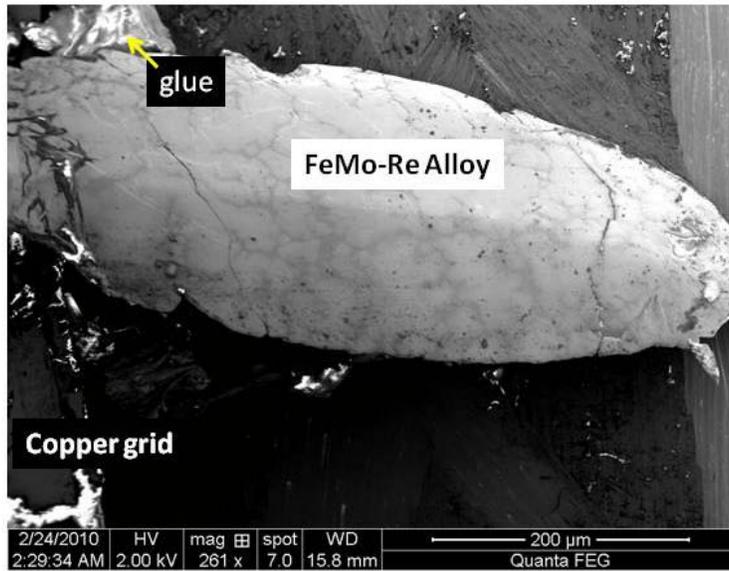

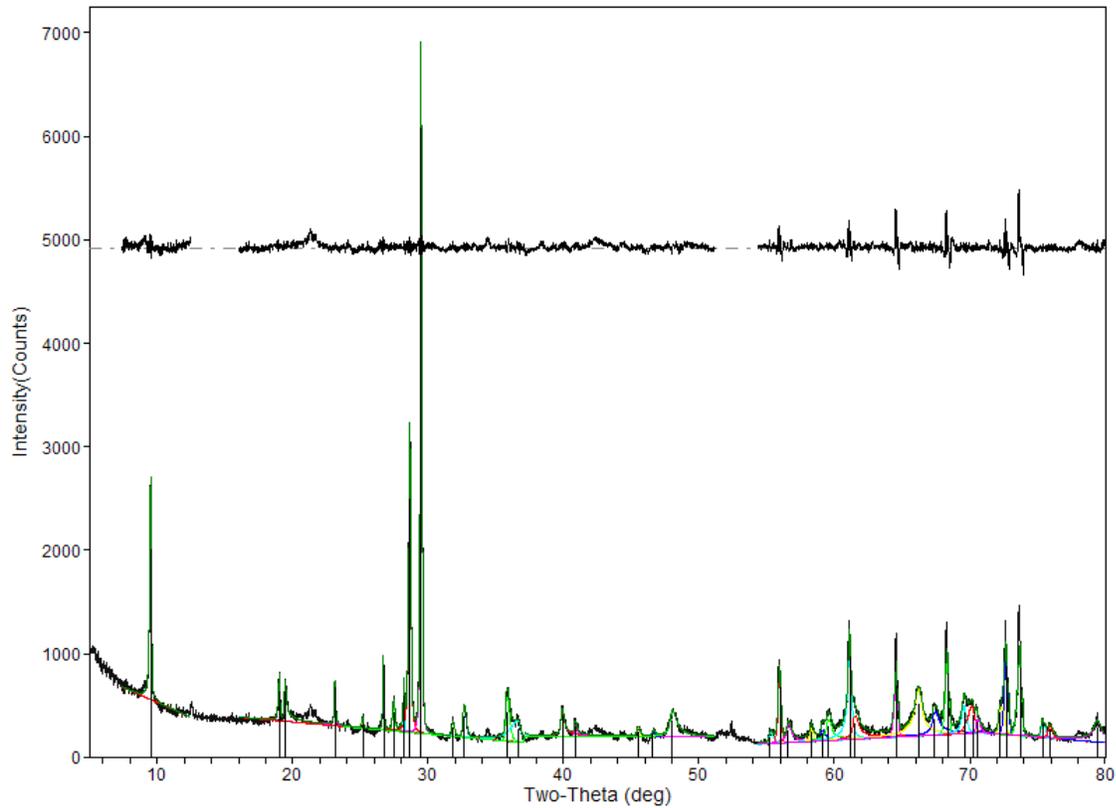

Figure 2.8 SEM image of specimen to be examined with TEM.

### 3. X-ray Diffraction

Profile fit

Profile fitting of the observed powder pattern.

The list below is obtained via this fit.

 CELL: 9.38375 x 9.38375 x 18.6865 <90.0 x 90.0 x 120.0> Vol=1425.0  
 R=45.29%

Raw XRD data – red line; simulated based on the hexagonal cell above – blue line; black line – the difference between the observed and the calculated data (based on the cell above).

#### 4. CONCLUSIONS

The FeMo-Re alloy exhibited four phases. The molybdenum-bearing composition occurs as large separate phase. Based on composition, this molybdenum-rich phase does not appear to be un-melted molybdenum. The rhenium-rich and the rhenium-poor regions dominate the rest of the material. Inter-dispersed ferrite occurs throughout the remainder of the material. This FeMo-Re alloy along with the FeMo-Tc alloy will be examined in more detail as soon as the TEM instrument is available.
