Summary

The purpose of this project was to perform a finite element analysis of a pressurized water reactor pressurizer surge nozzle mock-up to predict both the weld residual stresses created in its construction and the final stress state after the application of the Mechanical Stress Improvement Process (MSIP). Strain gages were applied to the inner diameter of the mock-up to record strain changes during the MSIP. These strain readings were used in an attempt to calculate the final stress state of the mock-up as well.

The presentation of the data shows the difficulty in calculating the final stress state based on strain gage measurements in a structure that has experienced yielding stress cycles and has built in residual stresses be they from welding or a yield inducing process like the MSIP. A comparison of the axial and hoop stress values calculated from the strain gage data using three different methods were compared to the finite element analysis predictions. These results show the differences in calculated stresses found when using different assumptions about the initial stress state of the mock-up.

The strain gage measurements indicate that both the axial and hoop stresses in the area of the Alloy 82/182 weld are made compressive by the MSIP process with each of the calculation methods examined.

1.0   Introduction

   The purpose of this project was to perform a finite element analysis of a pressurized water reactor pressurizer surge nozzle mock-up to both predict the weld residual stresses created in its construction and the final stress state after the application of the Mechanical Stress Improvement Process (MSIP). Strain gages were applied to the inner diameter of the mock-up to record strain changes during the MSIP. These strain readings were used in an attempt to calculate the final stress state of the mock-up.

2.0   Discussion of Mechanical Stress Improvement Process

The MSIP has been used for many years to mitigate intergranular stress corrosion cracking (IGSCC) found in boiling water reactors (BWRs) which have austenitic stainless steel piping and welds. The MSIP was developed and first patented in 1986 (O'Donnell and Porowski 1986; Porowski et al. 1987) by O'Donnell and Associates Inc. Currently the patent is held by NuVision Engineering.

The MSIP tool applies a quasi-radial mechanical loading around the pipe circumference and is positioned to one side of the weld to be treated. The distance from the weld centerline to the MSIP tool is in the range of 25 to 100 mm (1 to 4 inches) depending on the geometry. The tool hydraulically squeezes the pipe and is displacement-controlled by the use of shims. The loading plastically deforms the pipe in compression under the tool which creates beneficial compressive stresses on the inside diameter of the adjacent welded region.

The MSIP effect has been extensively documented in two Electric Power Research Institute (EPRI) reports. In the earliest report, dating from 1987, large diameter (28-inch diameter) pipes were welded and tested (Smith et al. 1987). The scope of the testing was designed to determine the MSIP's change of weld stress patterns, the effect on pre-existing defects, and the effect on the detectability of pre-existing defects after the process. The later report, from 1993, documents experiments on smaller diameter (12-inch diameter) nozzle geometries (Phillips et al. 1993). Both studies found similar results. Smith et al. (1987) measured as-welded, inner diameter, axial tensile stresses in the 275 MPa to 414 MPa (40 ksi to 60 ksi) range, which were uniformly converted to compressive stresses in the -69 MPa to -241 MPa (-10 ksi to -35 ksi) range after application of the MSIP.

Figure 2.1 shows the schematic of the application of the MSIP on a surge nozzle geometry. The original patent (O'Donnell and Porowski 1986) for the process states that the permanent reduction of the diameter of the pipe at the mid-plane of the applied load should be 0.2 to 2.0 percent. In this study a baseline value of 1% reduction in diameter was used for the analysis and 0.94% was achieved during the test on the mock-up. The patent also states that the distance between the mid-plane of the weld to be treated and the mid-plane of the load application site should be 2 to 12 times the pipe thickness. The edge of the applied MSIP load band should be at least equal to half the wall thickness away from the weld centerline.

The MSIP has been used successfully on over 1,300 welds, including more than 500 nozzle safe end geometries in over 30 BWR units and now in pressurized water reactor (PWR) units as well according to NuVision Engineering the holder of the patent on the MSIP process.
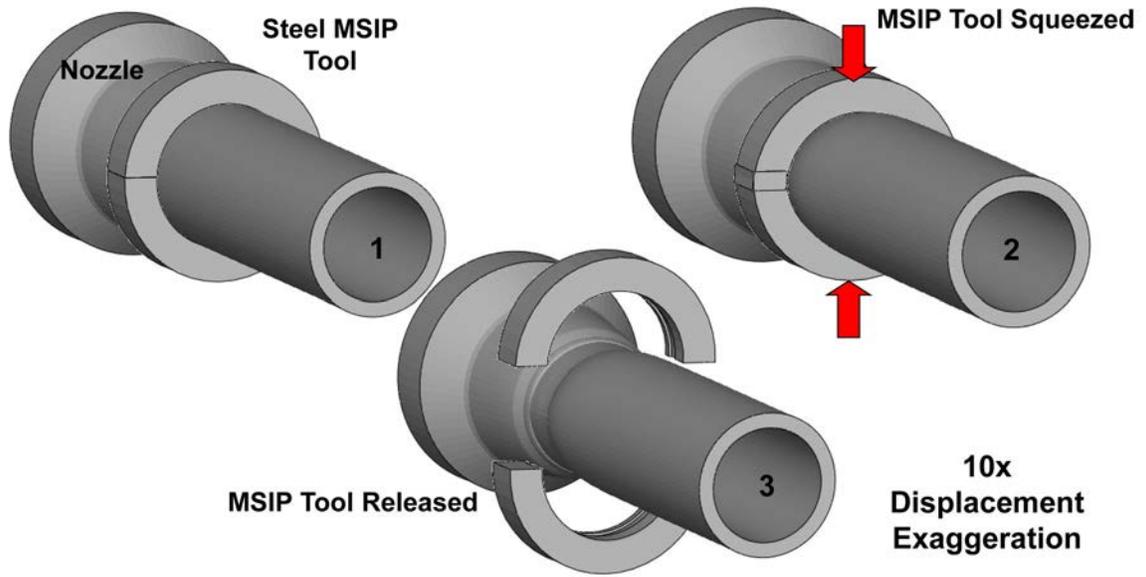

Figure 2.1. Mechanical Stress Improvement Process

3.0 Technical Approach of Finite Element Modeling

Two dimensional axi-symmetric finite element models were used to calculate the weld residual stresses in the treated weld. The use of axi-symmetric models allowed for finer mesh refinement and computational efficiency in running the multiple load cases and sensitivity studies that were conducted. The MSIP is not truly axi-symmetric in its application. Three-dimensional models of the MSIP were not evaluated in this study but were used on a similar geometry in a previous study (Fredette et al. 2008; Fredette and Scott 2009). Three dimensional models of the process have shown that even though the MSIP application does not produce a uniform effect around the circumference of the pipe; it is effective over the entire circumference of the treated weld. Strain gage placement at 90° circumferential spacing was used to capture this effect.

Preceding evaluations of the MSIP have been conducted using physical test specimens and axi-symmetric finite element models (Smith et al. 1987; Phillips et al. 1993). The process, as illustrated in Figure 2.1, uses two 180° spacers to squeeze the pipe segment. The spacers are held in a fairly rigid steel structure, and pulled together with hydraulic pistons. The spacers are made to conform to the geometry of the pipe system, a nozzle in this case. The radial gap between the spacer and the pipe segment to be treated is made to further conform to the pipe shape with crushable waffled stainless steel shims. The purpose of the crushable shims is to make the loading more uniformly radial by conforming to surface irregularities on the pipe.

3.1 Pressurizer Surge Nozzle Geometry

Figure 3.1 shows a revolved version of the axi-symmetric pressurizer surge nozzle mock-up geometry with the weld area highlighted. The nozzle is carbon steel; the butter (green in the figure), dissimilar metal weld (maroon in the figure) are made from Alloy 82/182; and the safe end, secondary stainless steel weld (orange in the figure), and pipe are made from 300 series stainless steel material.
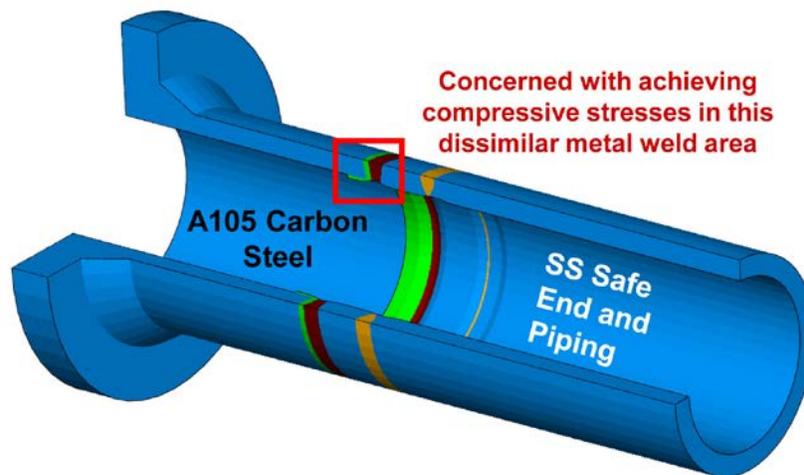

Figure 3.1. Pressurizer Surge Nozzle Mock-Up Geometry Used in Analysis

3.2 Material Data

The material properties used for the thermal and structural analysis for the Alloy 82/182 weld metal, the reactor vessel steel nozzle material, and the 300 series stainless steels are shown in Tables 3.1 to 3.3. Figures 3.2 through 3.4 illustrate the temperature dependent elastic plastic properties for the Alloy 182 weld material, A508 Grade 2 carbon steel, and 300 series stainless steel, respectively, used in the analyses. The ABAQUS isotropic material hardening laws were followed using the material true stress-strain data presented here. The solution annealed tensile properties for Alloy 182 were obtained in a prior program by Oak Ridge National Laboratory (ORNL). The elastic-plastic properties for the A508 Grade 2 steel were obtained from the literature, and the stainless steel properties were obtained from prior work done at Battelle. It is important to note that stress relieved and annealed weld material must be used to obtain elastic-plastic tensile properties of the weld material. The welding simulation process subsequently creates work hardening of the material. Finally, Table 3.4 shows creep properties used to model stress relaxation during the post weld heat treatment.

3.3 Weld Residual Stress Modeling Details

The welding produced residual stresses were calculated using an axi-symmetric model. The finite element model was subjected to a thermal analysis, which simulated the weld process functions of laying down the molten beads of weld filler metal, introducing heat energy into the weld bead and cooling the weld to an appropriate inter-pass temperature. The thermal analysis calculated the temperatures throughout the finite element model through the welding process. A subsequent stress analysis was performed which used the previously defined temperatures to calculate the elastic-plastic residual stresses and strains in the welded geometry due to the thermal effects of welding. ABAQUS finite element software was used throughout the study. Material properties used in the analyses varied with temperature and made use of the annealing simulation capabilities of the ABAQUS software to model weld bead melting (Dassault Systèmes 2007).

Figure 3.5 shows the pressurizer surge nozzle mock-up axi-symmetric geometry. This configuration contained a low alloy steel nozzle and a welded Alloy 82/182 buttering on the end. The stainless steel safe end component was welded to the buttered nozzle with Alloy 82/182 weld filler. After the primary Alloy weld was completed, a standard practice is to grind out the root pass and re-weld that area. This process tends to increase the inner diameter axial tension stresses and was modeled in the analysis. In the mock-up, pre-made flaws were welded into the inner diameter of the Alloy 82/182 weld for non-destructive examination purposes and this inner diameter welding would produce a similar tension increasing effect. In close proximity to the Alloy 82/182 weld is another weld fabricated with stainless steel weld filler material which connects the stainless steel safe end to the stainless steel piping.
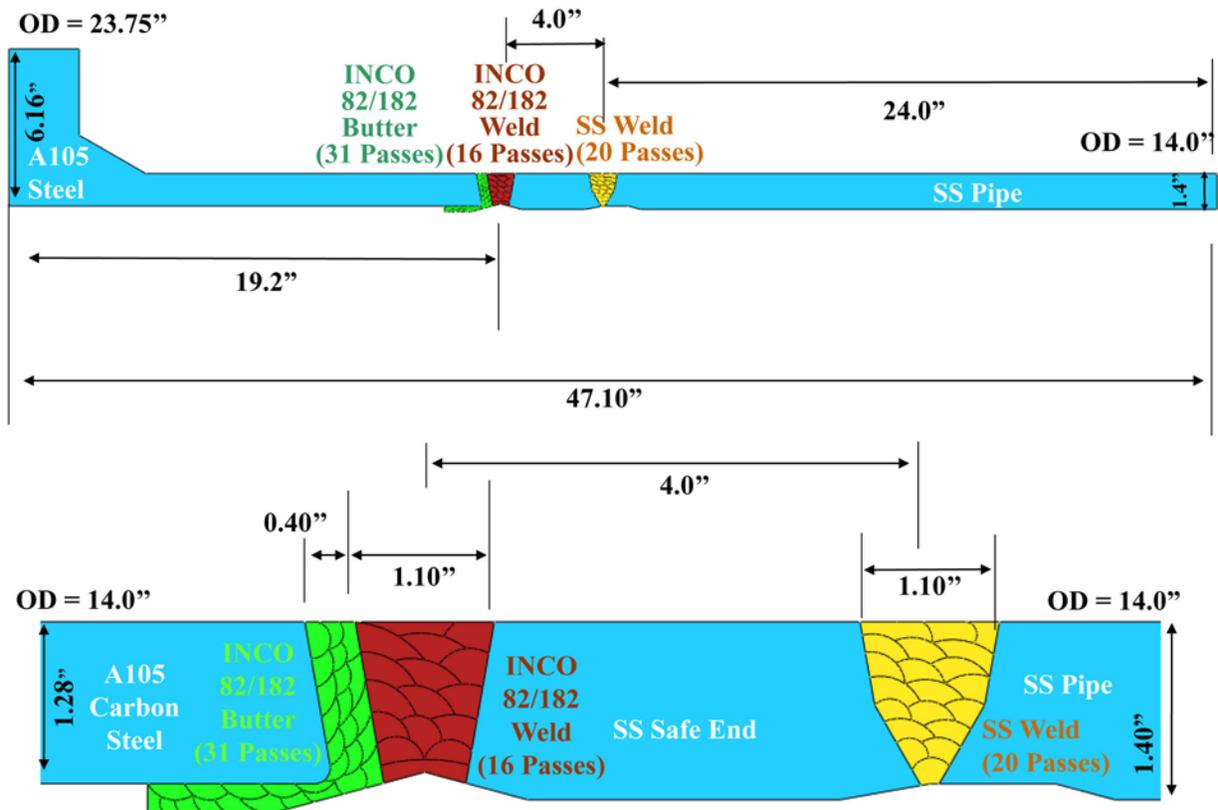

Figure 3.5. Surge Nozzle Geometry, Materials, and Weld Layout

Figure 3.6 shows the transient thermal analysis steps used to model the thermal portion of the weld residual stress analysis for an example surge nozzle geometry. Between weld passes, the weld was allowed to cool to an inter-pass temperature of 66°C (150°F). The root pass of the Alloy 82/182 weld was ground out and re-welded as a final step in the weld process. This step is not always performed during plant fabrication, but was included here because it increases the interior tension stresses in the weld and is thus conservative. The inner diameter grinding and welding of the flaws into this mock-up provide a similar process that increases inner diameter tensile stresses. It is unclear whether the entire root pass was ground out in the mock-up, but portions of it were removed and re-welded in the final steps of the welding process to implant pre-made flaws to be used in a non-destructive examination test.
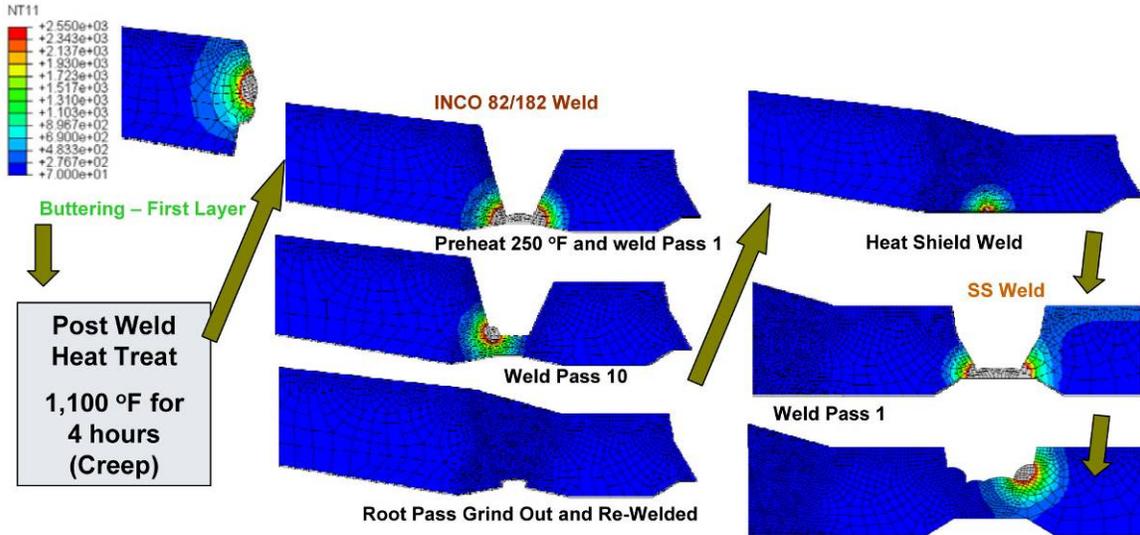

Figure 3.6. Details of the Welding Residual Stress Thermal Modeling (°F)

Figure 3.7 shows the schematic of the axi-symmetric application of the MSIP. The original patent for the process states that the permanent reduction of the diameter of the pipe at the mid-plane of the applied load should be 0.2 to 2.0%. In this study a baseline value of 1% reduction in diameter was used and further evaluated through sensitivity analyses. The patent also states that the distance between the mid-plane of the weld to be treated and the mid-plane of the load application site should be 2 to 12 times the pipe thickness. The edge of the applied MSIP load band should be at least equal to half the wall thickness away from the weld centerline.
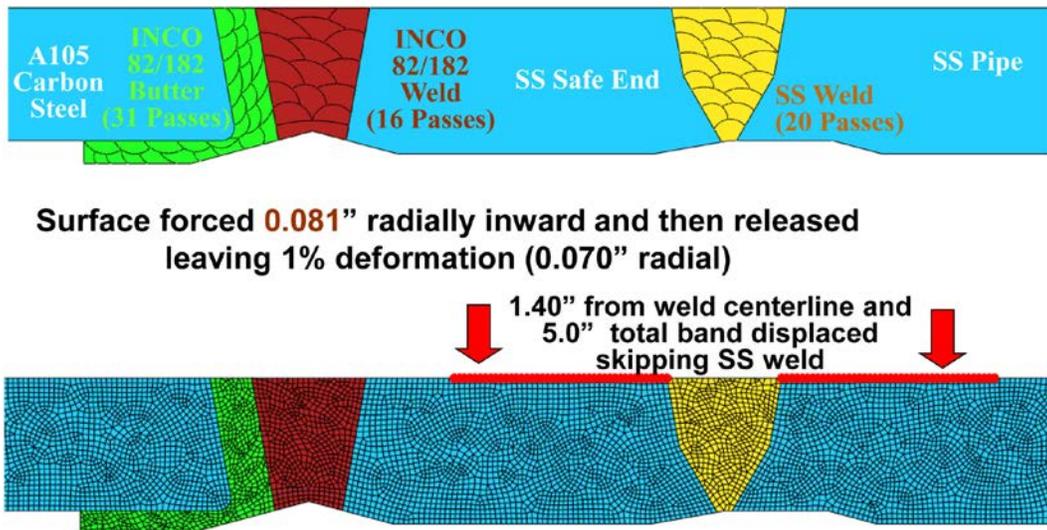

Figure 3.7. Surge Nozzle MSIP Application

The values used for this nozzle comply with the requirements described in the original patent (Porowski et al. 1987) and fall in the typical range of 1% reduction in diameter, two times the wall thickness between midpoints, and one times the wall thickness to the edge of the load application site. When the application location of the MSIP falls over the location of the secondary weld, as is this case, a gap is made in the tool to avoid the crown of the secondary weld as shown in the figure, and included in the tooling used on the mock-up.

4.0   Results from both Finite Element Analysis and Strain Gage Measurements

The pressurizer surge nozzle weld residual stresses were developed as shown in Figure 3.6. Though described previously in some detail, the process deserves another explanation here. The figure shows the initial welding of the butter layer plus the post weld heat treatment of the buttered nozzle at 593°C (1,100°F) for four hours during which creep properties are allowed to relax the welding residual stresses in the butter layer. The butter layer is then pre-heated to 121°C (250°F), and the dissimilar metal weld is then built up pass-by-pass until the weld is complete as shown in Figure 3.7. This process joins the stainless steel safe end to the carbon steel nozzle. The dissimilar metal weld (DMW) is allowed to cool to approximately 66°C (150°F) between passes and to room temperature after the weld is complete. The root pass is then ground out and re-welded. When the Alloy 82/182 weld is complete and cooled to room temperature, the secondary stainless steel weld is built up and then allowed to cool to room temperature once completed.

Figure 4.1 shows the axial stress contour plot after the Alloy 82/182 welding is complete (top figure), after the stainless steel safe end weld is complete (middle figure), and after the MSIP has been performed (bottom figure). Figure 4.2 shows the axial stress along the inner diameter of the mock-up with the location of the butter, Alloy 82/182 weld, and stainless steel weld indicated by vertical color coded bands in the graph.
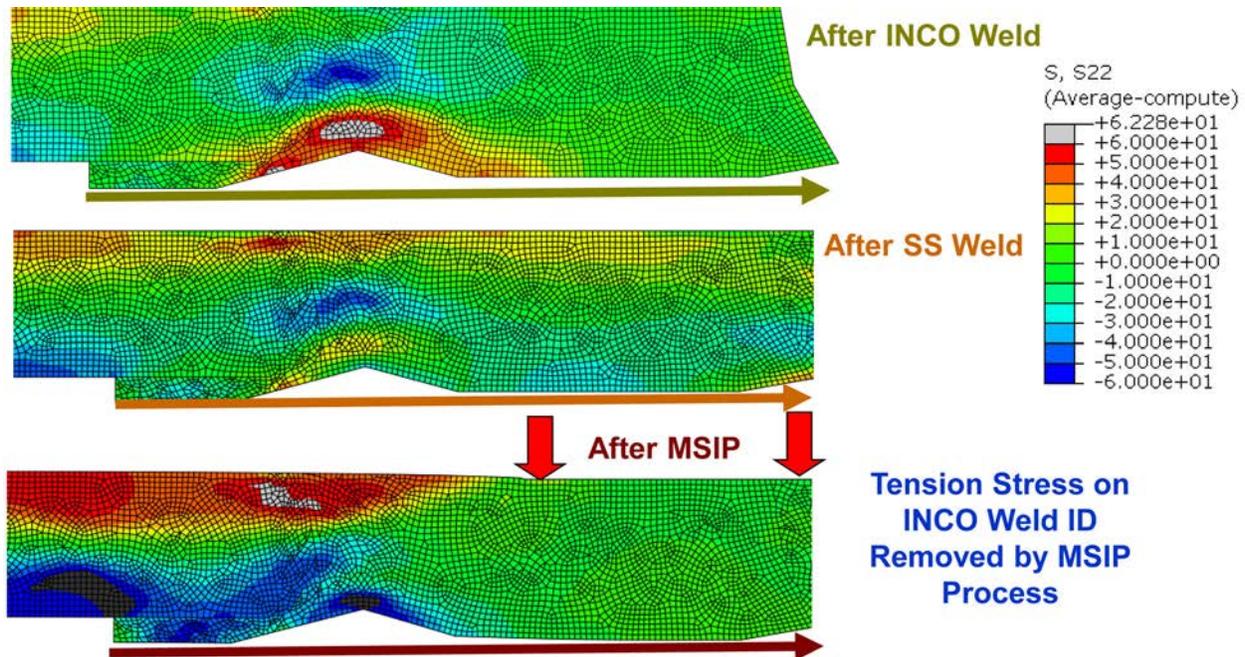

Figure 4.1. Surge Nozzle Axial Stress (ksi)
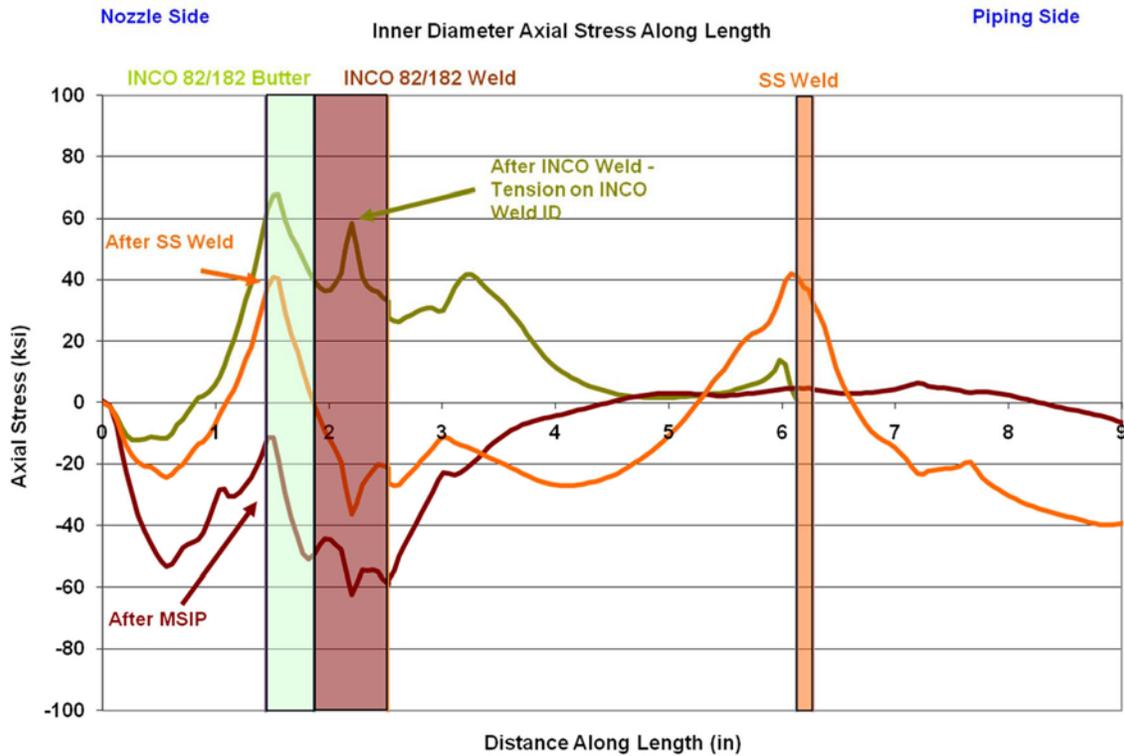

Figure 4.2. Surge Nozzle Mock-Up Axial Stresses along the Inner Diameter

One can see that the stress was very high in the butter and dissimilar metal weld before the secondary stainless steel weld is made. Once the secondary stainless steel weld is completed, the stresses along the inner diameter are primarily compressive except in the area of the transition between the carbon steel nozzle and the butter. In this area the stresses remain tensile in the range of 40 ksi (276 MPa). After the MSIP is completed, all of the stresses along the inner diameter have been made compressive up to the location of the secondary stainless steel weld.

The PWSCC occurrences are typically found in the dissimilar metal weld at the interface between the pressure vessel steel material and the butter layer, or between the butter and the Alloy 82/182 weld. The weld residual stresses in the stainless steel weld are of less importance.

Figure 4.3 shows the hoop stress contour plots and Figure 4.4 show the inner diameter hoop stress along the length of the dissimilar metal weld area of the surge nozzle. The graph shows that hoop stresses are very high on the inner diameter before the secondary stainless steel weld is made, and are reduced, but remain highly tensile after the stainless steel weld is completed. The stresses remain high in the area of the butter transition to the carbon steel nozzle. The MSIP reduces the hoop stresses in the area of concern to be compressive over the whole length of the dissimilar metal weld area.
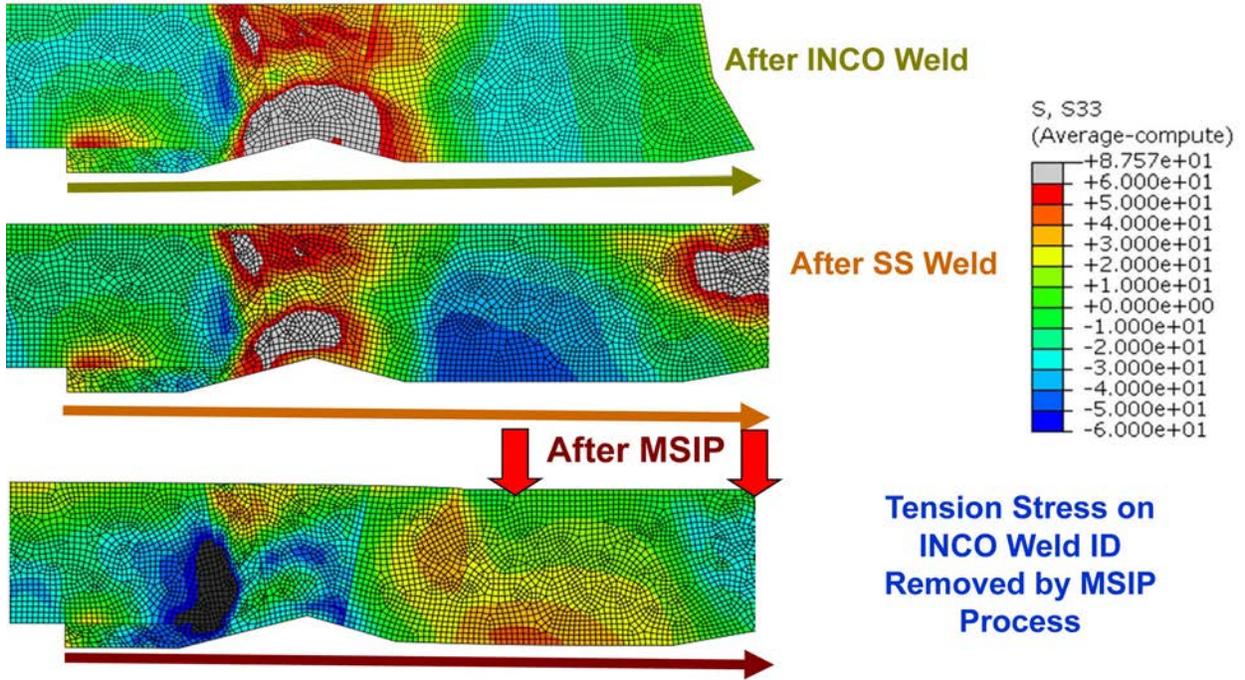

Figure 4.3. Surge Nozzle Inner Diameter Hoop Stress Path (ksi)
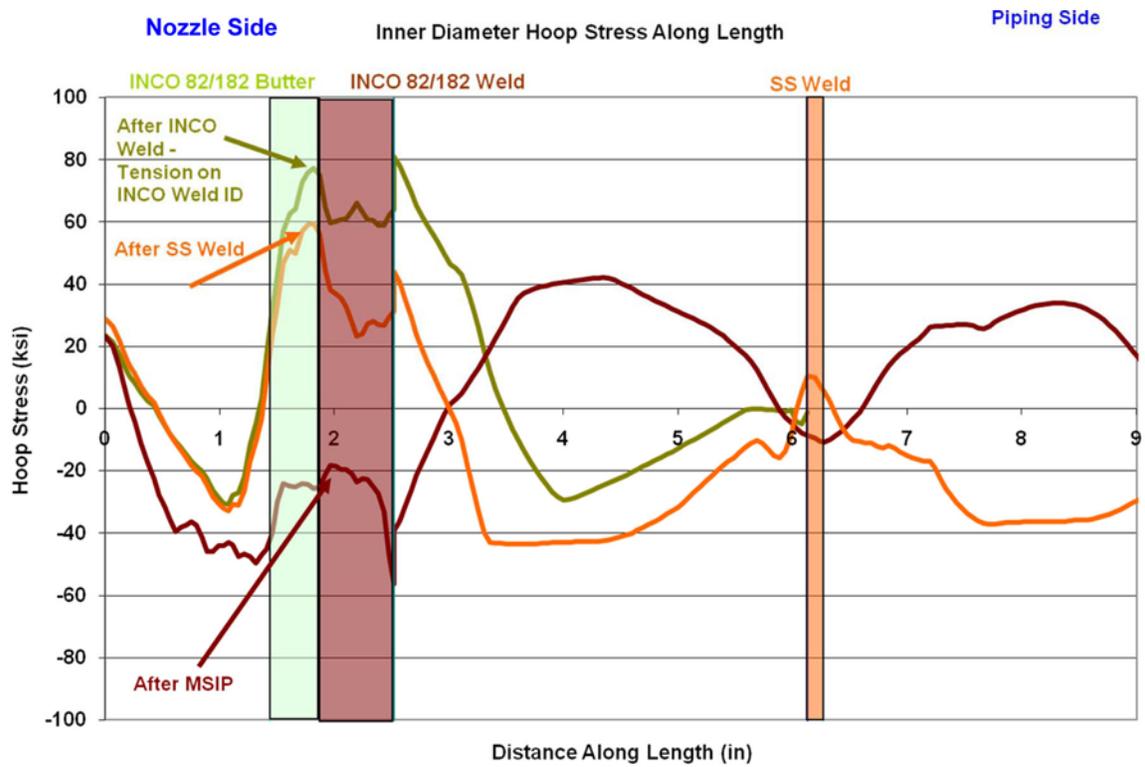

Figure 4.4. Surge Nozzle Inner Diameter Hoop Stresses

4.1 Strain Gage Instrumentation

Figure 4.5 and Figure 4.6 show the clock position and axial position of the strain gages used to instrument the surge nozzle mock-up. The strain gages were placed at 0° and 90° with 0° being the top position in the MSIP process. Five locations were used at each angular position spaced one inch apart spanning the length of the safe end. In each of the locations, a 2-element, 90° biaxial rosette gage was used to measure both axial and hoop direction strains. Previous three-dimensional MSIP modeling has shown that the compressive hoop stress produced during and after the MSIP process so overwhelms the welding residual stresses, that the principal stresses in the area of measurement are in the axial and hoop directions. The gages were Vishay Micro-Measurements 0.032-in. gage, 120-Ohm strain gages. They each used three wires in a quarter bridge arrangement. Their gage factor was 2.06 and they were calibrated for the thermal expansion of steel. The gages were read with a Vishay Strain Indicator P-3500 that was calibrated at the Battelle instrument lab on April 15, 2009, and the next calibration was not due until May 15, 2010, five months after the test was done. Two Vishay Instruments SB-10 switch and balance units were used to wire up the twenty strain gages used in the test. The strain gage locations are numbered #1–#5 with #5 being closer to the Alloy 82/182 weld.

Figure 4.7 shows the strain gage installation at both 0° and 90°. The features on the inside surface of the mockup can be compared with the spacing shown in Figure 4.6.

Strain gages were set up at 0° and 90°.
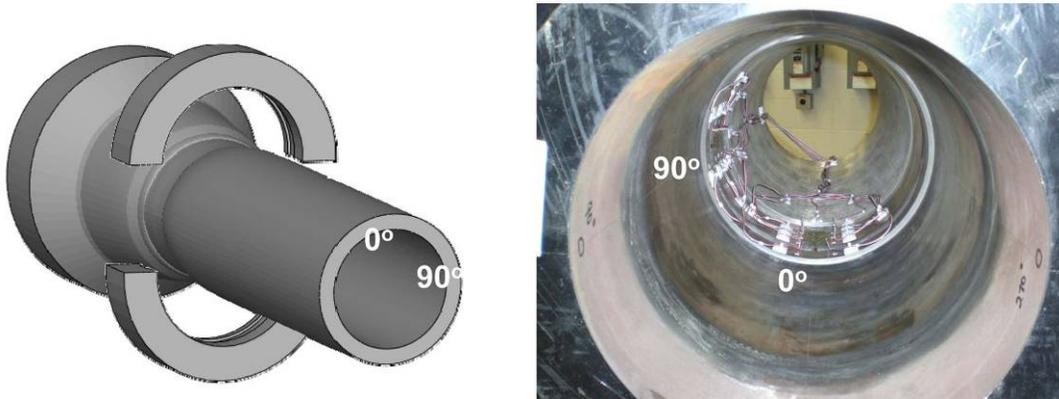

Figure 4.5. Strain Gage Clock Positions

* Strain gages were set up at 0° and 90°
 -- 5 positions at each angular location
 -- Readings in axial and hoop direction at each position
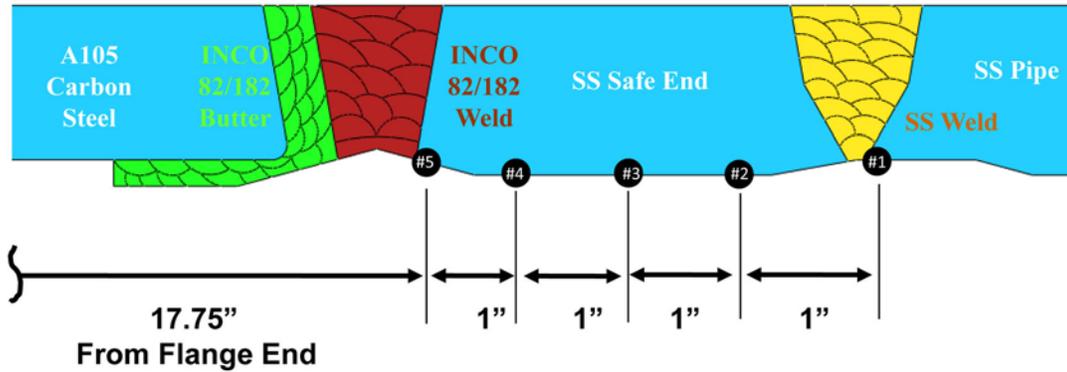

Figure 4.6. Strain Gage Axial Positions

* Strain gages were set up at 0° and 90°
 -- 5 positions at each angular location
 -- Readings in axial and hoop direction at each position
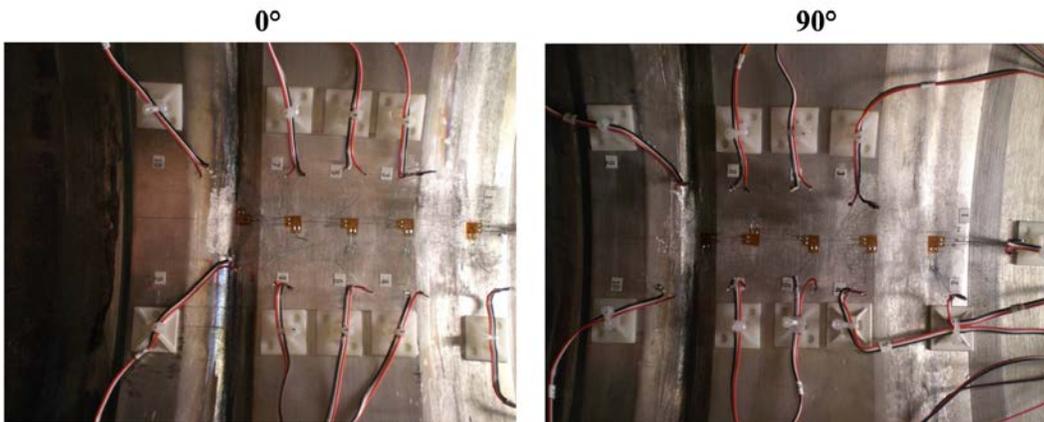

Figure 4.7. Strain Gage Installation

Figure 4.8 shows the axial strain gage readings vs. applied hydraulic pressure during the MSIP application. The graph looks like a typical stress strain plot showing yielding. Though strain gages at positions #2 and #3 in the 90° clock position failed at the highest MSIP load, the strain gages appeared to be working normally up to that point. The hoop strain gage results look similar, but all values are negative.

Figure 4.9 and Table 4.1 show the axial strain values plotted against two finite element model curves. The red dashed curve represents the finite element analysis (FEA) predicted axial strain in a case where there were no initial weld residual stresses, and MSIP was applied. The solid darker red curve represents the FEA predicted axial strain in the case in which weld residual stresses were present before the MSIP. The strain gage data matches the predictions reasonably well. The strain gage data shows similar results

4.5

to the FEA predictions and is a near perfect match in some locations. The values start out in compression near the Alloy 82/182 weld, and peak at 1% strain which is the permanent radial deformation caused by the MSIP, and then are reduced to values in the range of 0.5% strain similar to the FEA prediction with no initial weld residual stresses toward the safe end weld. The table shows that the axial strains are all positive except for locations #5 which are all negative. The table also shows that the strain is reduced for all positive cases after the MSIP tool is released, and the strain actually increases when the tool is released for the compressive locations #5.
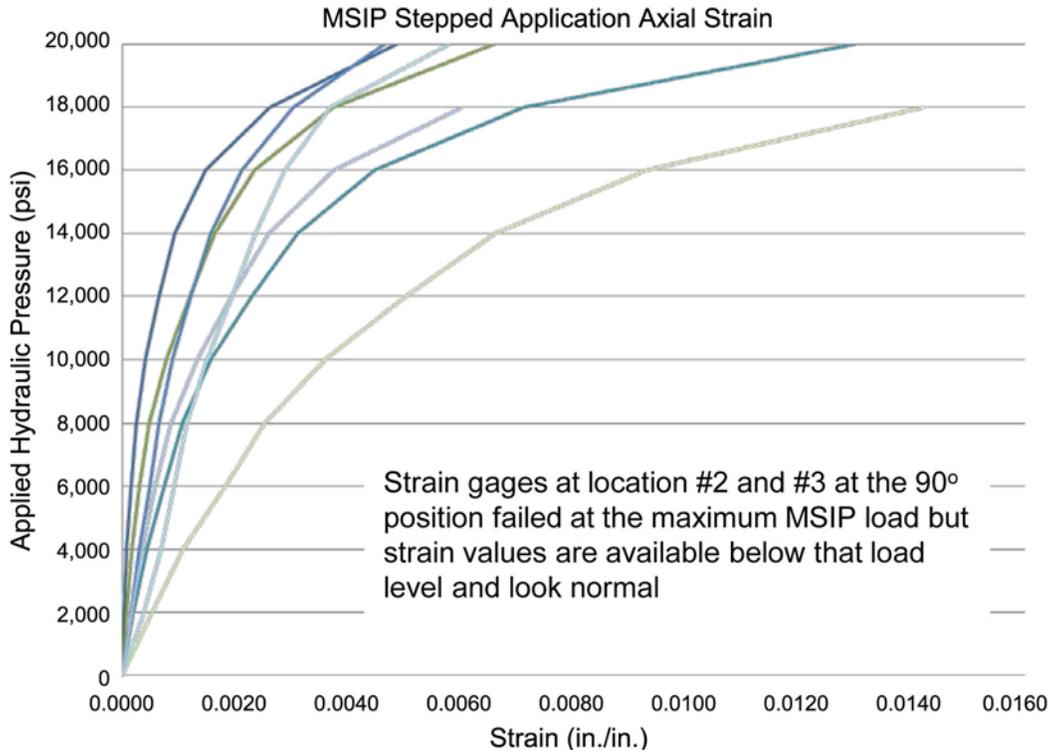

Figure 4.8. MSIP Hydraulic Pressure vs. Axial Strain Gage Readings
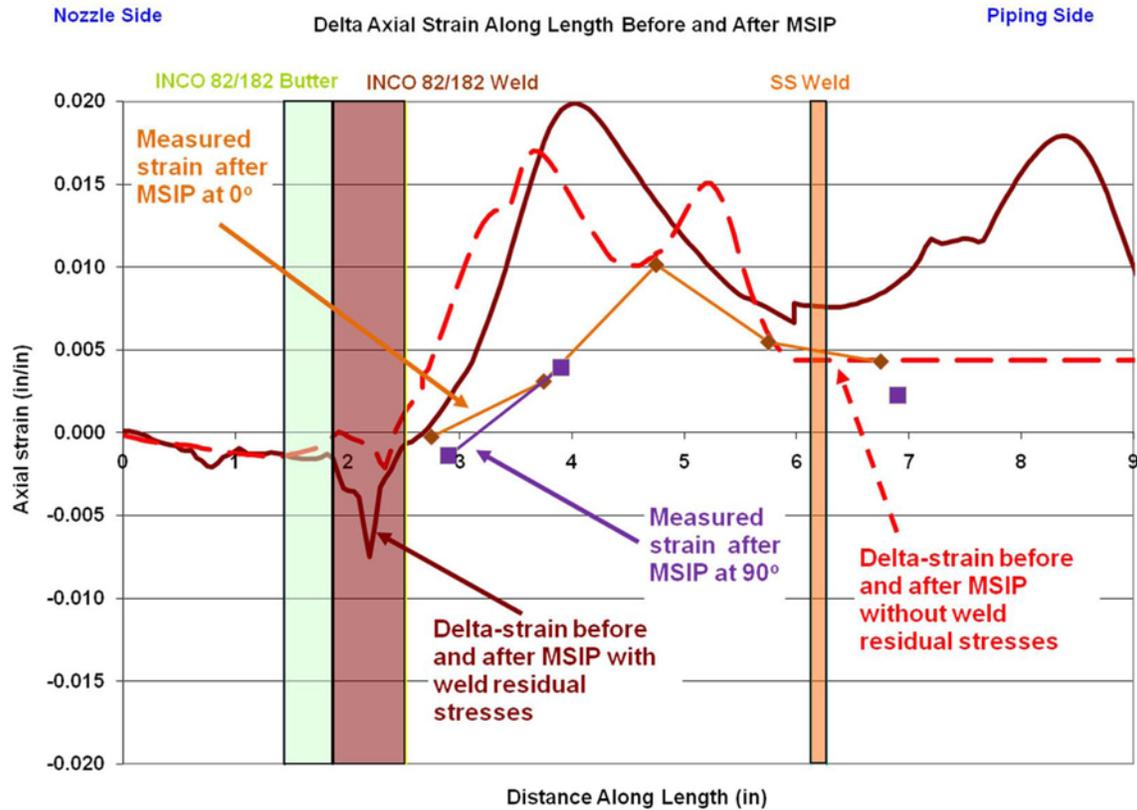

Figure 4.9. Post MSIP Axial Strain Gage Readings Plotted against FEA Predictions

Table 4.1. Axial Strain Gage Readings During and After MSIP

Gage Position Code	Axial Readings with MSIP Load Applied, in/in	Axial Readings after MSIP, in/in
0° #1 Axial	0.0049	0.0043
0° #2 Axial	0.0066	0.0055
0° #3 Axial	0.0130	0.0101
0° #4 Axial	0.0046	0.0031
0° #5 Axial	−0.0001	−0.0003
90° #1 Axial	0.0026	0.0022
90° #2 Axial	Failed	Failed
90° #3 Axial	Failed	Failed
90° #4 Axial	0.0058	0.0039
90° #5 Axial	−0.0012	−0.0014

Figure 4.10 and Table 4.2 show the hoop strain values plotted against the same two finite element model curves, but for hoop strain in this case. The red dashed curve represents the FEA predicted hoop strain in a case where there were no initial weld residual stresses, and MSIP was applied. The solid darker red curve represents the FEA predicted hoop strain in the case in which weld residual stresses were present before the MSIP. Again, the strain gage data matches the predictions reasonably well with the 90° location matching better than the 0° location. The values start out in compression near the Alloy

82/182 weld and remain in compression throughout. Their minimum points are between −1% and −1.5% strain which is the in the range of the permanent radial deformation caused by the MSIP, and then are reduced to values in the range of −0.5%–0.75% strain similar to the FEA prediction with no initial weld residual stresses. The table shows that the hoop strains are all negative. The table also shows that the strain is reduced considerably in all cases after the MSIP tool is released.
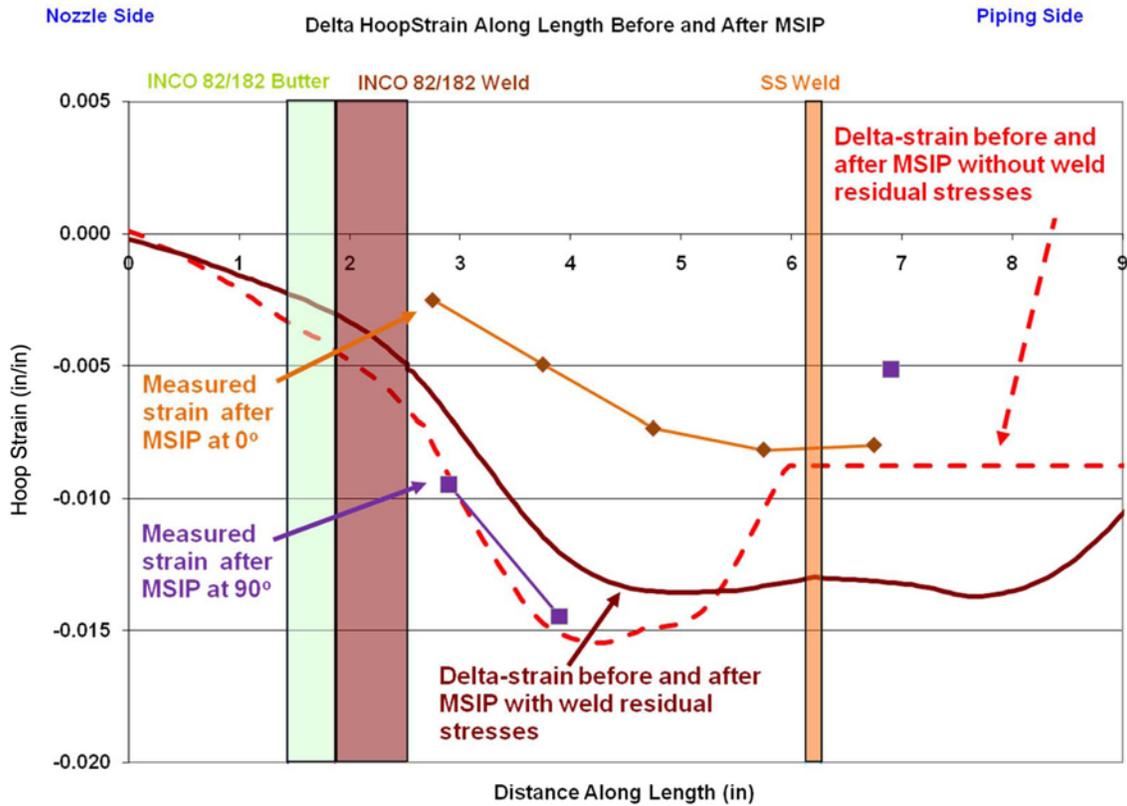

Figure 4.10. Post MSIP Hoop Strain Gage Readings Plotted against FEA Predictions

Table 4.2. Strain Gage Readings During and After MSIP

Gage Position Code	Hoop Readings with MSIP Load Applied, in/in	Hoop Readings after MSIP, in/in

4.2 Conversion of Strain Gage Readings to Stress Values

People are generally more comfortable working with stresses than strains, but the conversion of strain to stress values in cases in which there has been yielding, or in the cases of welding, with many yielding cycles, is not easy. Strain gages only give results for Δ-strain from the initial state in which the gages were applied. No valid stress results can be drawn without knowing the original stress state of the mock-up. To illustrate this point calculated stress values will be made with the following assumptions:

1. Using only the post MSIP strain values as other methods such as x-ray diffraction, neutron diffraction, and hole drilling would produce from a final strain state measurement.

2. Using the yielded stress state with the MSIP load applied, and the strain relaxation after the MSIP load was released to predict the final stress state assuming no initial weld residual stresses.

3. Using the FEA prediction for weld residual stress and yielding under the MSIP tool load and then calculating the final stress state by operating on these stress values with the measured strain relaxation (Δ-strain between the case with MSIP load applied and released.)

The following bi-linear stress-strain curve was used for the type 316 stainless steel shown in Figure 4.11. A similar curve was used for the FEA analysis. Isotropic strain hardening was assumed with linear stress relaxation following the Young's Modulus curve upon load release. Strain gage readings were converted to stress using the plane stress equations shown in Eq. (4.1) where stress is denoted by (σ), Young's Modulus is denoted by (E), strain is denoted by (ε), and Poisson's Ratio is denoted by (μ). Previous three-dimensional MSIP modeling has shown that the compressive hoop stress produced during and after the MSIP process so overwhelms the welding residual stresses, that the principal stresses in the area of measurement are in the axial and hoop directions.

Plane Stress Equations

$$\sigma_{Axial} = E\left(\frac{\varepsilon_{Axial} + \mu\varepsilon_{Hoop}}{1-\mu^2} \right)$$

$$\sigma_{Hoop} = E\left(\frac{\varepsilon_{Hoop} + \mu\varepsilon_{Axial}}{1-\mu^2} \right)$$

(4.1)

Bi-Linear Stainless Steel Stress-Strain

316 stainless values used in calculations

Young's Modulus =	28,400,000 psi
Poisson's Ratio =	0.294
Yield Strength =	41,040 psi
Ultimate Strength =	69000 psi
Strain at Ultimate =	0.1
Stiffness after yield =	283,699 psi
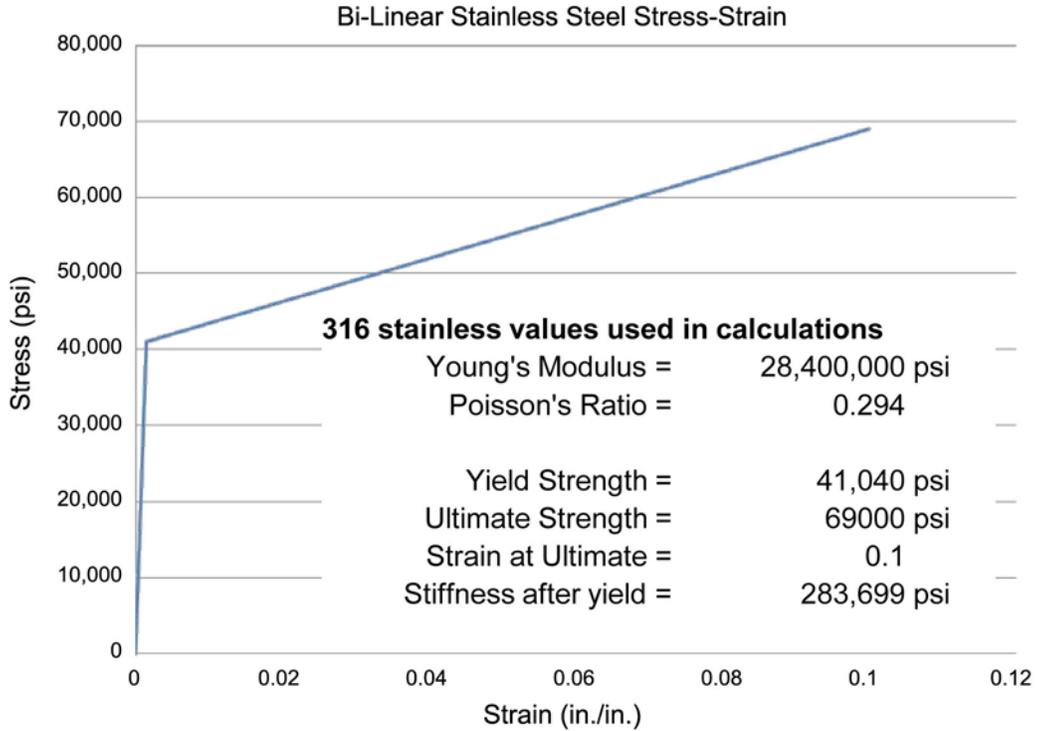

Figure 4.11. Bi-Linear Stress Strain Curve for 300 Series Stainless Steel

4.2.1 Conversion of Strain Gage Readings to Stress Values – Method 1. Disregarding Prior Yielding

The first method of converting strain readings to stress values disregards the prior yielding history of the mock-up and uses only the post MSIP strain values as other methods such as x-ray diffraction, neutron diffraction, and hole drilling would produce from a final strain state measurement. This calculation will produce an incorrect result because the original stress state, and the path through yielding caused by the MSIP tool is not taken into account. Stress is calculated following the bi-linear stress-strain curve shown in Figure 4.12 or the mirror image for compressive strains. The bi-axial stress equations are used considering both axial and hoop stresses and the Poisson's Ratio effects.
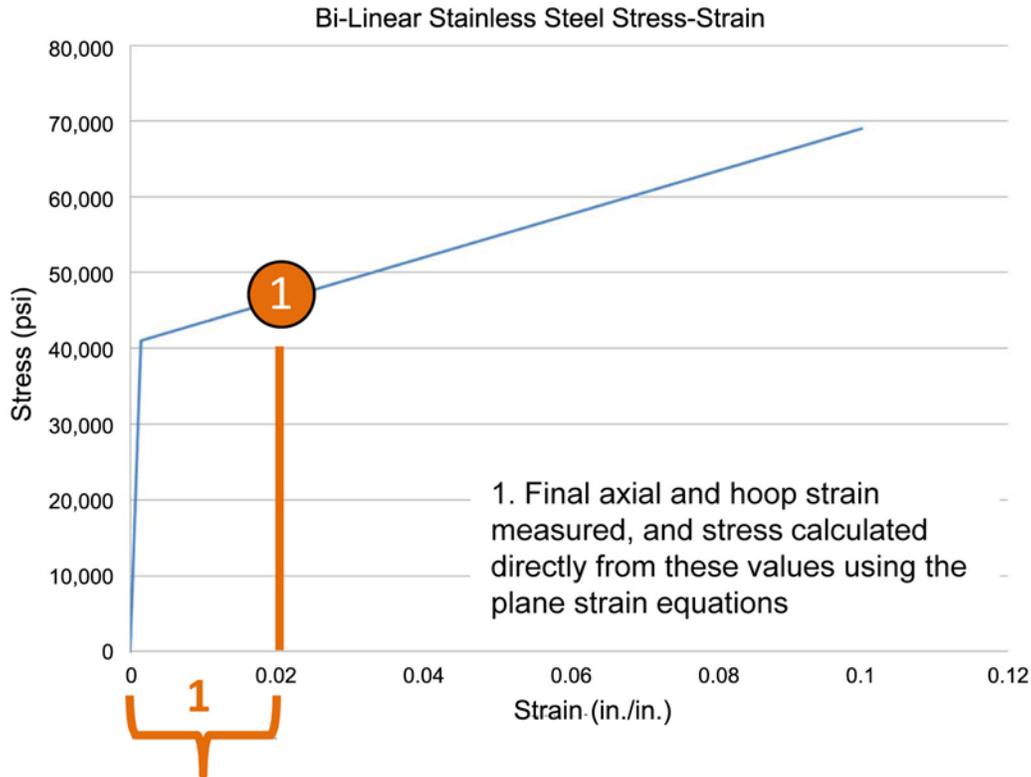

Figure 4.12. Method 1 – Strain to Stress Conversion

Figure 4.13, Figure 4.14, and Table 4.3 show the stress results from Method 1 vs. the finite element predictions for the case where there is only the stress caused by the MSIP process and no initial weld residual stresses. The axial stress plot, Figure 4.13, shows some agreement between the calculated stress from the strain data and the FEA model predictions. The values are compressive near the Alloy 82/182 weld, and tensile under the location where the MSIP tool is applied. There is a large spacing between the strain gage results at the two clock positions. The hoop stress plot, Figure 4.14, does show agreement between the gage results at each clock positions, but the results show uniform compressive stresses slightly beyond yielding and well below the values that the finite element analysis predicts.

90° #1	0.0022	−0.0051	22,990	−42,379
90° #2	Failed	Failed	Failed	Failed
90° #3	Failed	Failed	Failed	Failed
90° #4	0.0039	−0.0145	−9,628	−45,032
90° #5	−0.0014	−0.0095	−42,286	−44,000

4.2.2 Conversion of Strain Gage Readings to Stress Values – Method 2. Calculating Yielding Stress with MSIP Applied and then Relaxation after MSIP load is Removed from Strain Data Ignoring Weld Residual Stresses

The second method explored for converting strain readings to stress values uses the yielding strain caused by the MSIP application and then the strain relaxation afterward to predict the final stress state as shown in Figure 4.15. The bi-axial stress equations are used considering both axial and hoop stresses and the Poisson's Ratio effects. A calculation of the Von Mises stress for each of the strain gage positions shows that they are all well beyond the yield point when the MSIP load is applied. This result should be closer to correct, but still disregards the initial weld residual stresses in the mock-up.

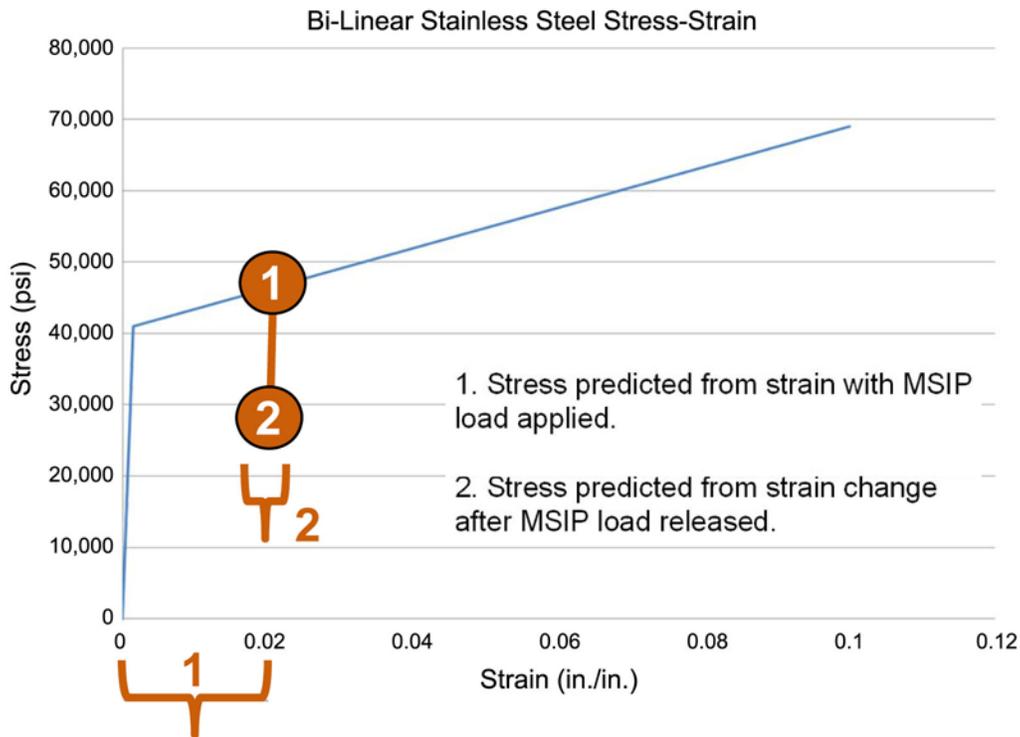

Figure 4.15. Method 2 – Strain to Stress Conversion

Figure 4.16, Figure 4.17, and Table 4.4 show the stress results from Method 2 vs. the finite element predictions for the case where there is only the stress caused by the MSIP process and no initial weld residual stresses. The axial stress plot, Figure 4.16, shows better agreement between the calculated stress from the strain data and the FEA model predictions. The values are compressive near the Alloy 82/182 weld, and tensile under the location where the MSIP tool is applied. The slope of the curve near the Alloy 82/182 weld better matches that of the FEA prediction, and the values from the two clock positions are closer together. The hoop stress plot, Figure 4.17, now do not show agreement between the clock positions, but the slope of the curve near the Alloy 82/182 weld is similar between them. The 0° location shows better agreement with the FEA prediction with compressive values near the Alloy 82/182 weld.

4.2.3 Conversion of Strain Gage Readings to Stress Values – Method 3. Using FEA Predicted Stress with Weld Residual Stress and MSIP Applied and then Calculating Relaxation after MSIP load is Removed from Strain Gage Data.

The third method uses the FEA prediction of weld residual stresses and the additional yielding caused by the application of the MSIP load as a starting point. The final stress state is calculated using the strain gage data and the Δ-strain measured between the case with the MSIP load applied, and when it is released. Figure 4.18 graphically shows the concept of the calculation. Stress and strain in steps #1 and #2 are predicted by the finite element model, and the delta strain and stress between steps #2 and #3 are calculated from the strain gage data. This method will give stresses closest to reality because of the inclusion of initial weld residual stresses but depends on the accuracy of the finite element model as a starting point.
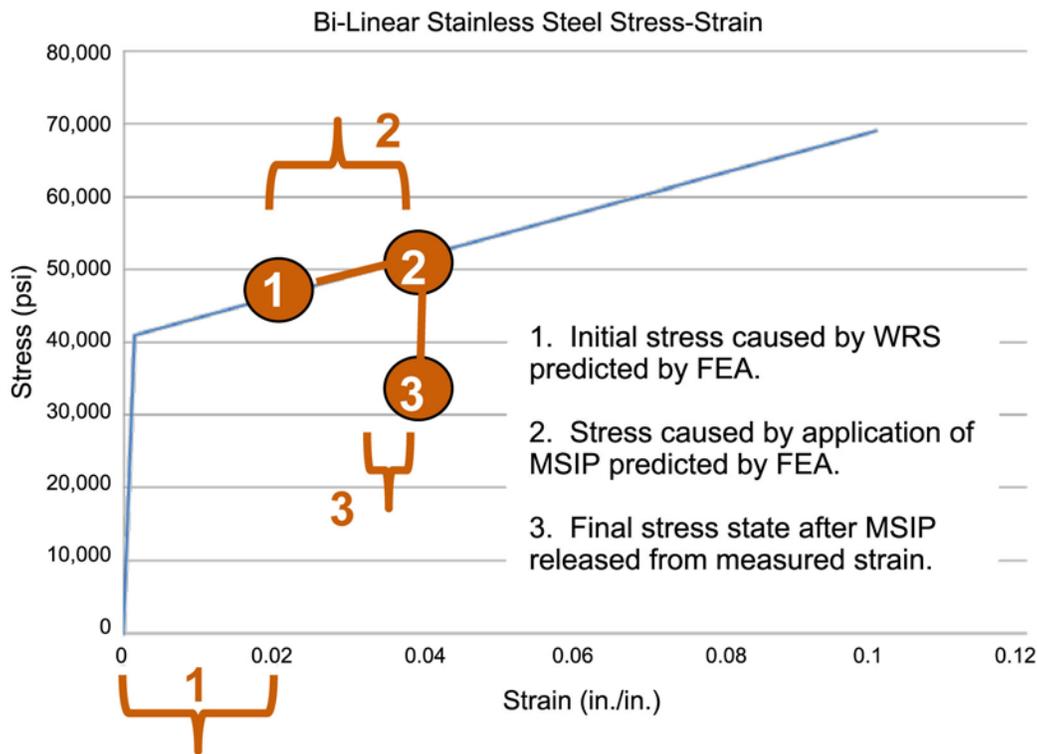

Figure 4.18. Method 3 – Strain to Stress Conversion

Figure 4.19, Figure 4.20, and Table 4.5 show the stress results from Method 3 vs. the finite element predictions for the case where weld residual stresses and the stress caused by the MSIP process are considered. The axial stress plot, Figure 4.19, shows very good agreement between the calculated stress from the strain data and the FEA model predictions. The values are compressive near the Alloy 82/182 weld, and slightly tensile under the location where the MSIP tool is applied. The slope of the curve near the Alloy 82/182 weld matches very well that of the FEA prediction. The values from the two clock positions are fairly close together. The hoop stress plot, Figure 4.20, shows very good agreement between

the finite element analysis results and the strain gage predictions. The slopes between the measured points and the finite element analysis predicted curve are very similar over the whole span of measured length. The data in Table 4.5 shows that the stress relaxation from the state with the MSIP load applied to the final stress state is not insignificant. There is a relaxation in axial stress of over 60 ksi (414 MPa) at one strain gage location and there are four hoop locations with stress relaxations of over 60 ksi (414 MPa), with one being almost 100 ksi (689 MPa). Despite these large changes in stress state from the as loaded case, the results for the final calculated stress state match the finite element predictions well.

4.19

5.0 Conclusion

This project used finite element analysis of a pressurized water reactor pressurizer surge nozzle mock-up to predict both the weld residual stresses created in its construction and the final stress state after the application of the Mechanical Stress Improvement Process (MSIP). Also, strain gages were applied to the inner diameter of the mock-up to record strain changes during and after the application of the MSIP. These strain readings were used in an attempt to calculate the final stress state of the mock-up as well.

The presentation of the data shows the difficulty in calculating the final stress state based on strain gage data in a structure that has experienced yielding stress cycles and has built in residual stresses be they from welding or a yield inducing process like the MSIP. Figures 5.1 and 5.2 show a comparison of the axial and hoop stress values calculated from the strain gage data using the three different methods discussed previously compared to the finite element analysis predictions. The results calculated for the axial stress at strain gage #3 at the 0° position is suspected of providing a faulty delta-strain measurement between the load cases in which the MSIP was applied and after it was released. The axial stress graph indicates results as solid lines with strain gage #3 data removed for Method #2 and Method #3 in which the delta-strain measurement is used in the calculation of stress. Dashed lines indicate the suspected faulty results provided by strain gage #3. The suspected faulty measurement is only evident after comparison of the stress calculations, and with the knowledge that strain gages #2 and #3 in the 90° position failed before the full MSIP load was applied at a similar strain reading of 1.3-1.4% (see Table 5.1 for raw strain measurements). This only further illustrates the care that must be taken in reviewing strain measurements in such a residual stress field.

In all cases examined, the strain gage measurements indicate that both the axial and hoop stresses in the area of the Alloy 82/182 weld are made compressive by the MSIP process.
