Summary

Over decades of operation, the U.S. Department of Energy (DOE) and its predecessors have released nearly 2 trillion L (450 billion gal.) of liquid into the vadose zone at the Hanford Site. Much of this discharge of liquid waste into the vadose zone occurred in the Central Plateau, a 200 km² (75 mi²) area that includes approximately 800 waste sites. Some of the inorganic and radionuclide contaminants in the deep vadose zone at the Hanford Site are at depths below the limit of direct exposure pathways, but may need to be remediated to protect groundwater. The Tri-Party Agencies (DOE, U.S. Environmental Protection Agency, and Washington State Department of Ecology) established Milestone M-015-50, which directed DOE to submit a treatability test plan for remediation of technetium-99 (Tc-99) and uranium in the deep vadose zone. These contaminants are mobile in the subsurface environment and have been detected at high concentrations deep in the vadose zone, and at some locations have reached groundwater. Testing technologies for remediating Tc-99 and uranium will also provide information relevant for remediating other contaminants in the vadose zone. A field test of desiccation is being conducted as an element of the DOE test plan published in March 2008 to meet Milestone M-015-50. The active desiccation portion of the test has been completed. Monitoring data have been collected at the field test site during the post-desiccation period and are reported herein. This is an interim data summary report that includes about 3 years of post-desiccation monitoring data. The DOE field test plan proscribes a total of 5 years of post-desiccation monitoring.

The desiccation field test was conducted at the Hanford Site 200-BC-1 Operable Unit. This waste site contains 26 cribs and trenches that received about 110 million L (29 million gal.) of liquid waste primarily in the mid-1950s. The waste contained about 410 curies of Tc-99. There is no evidence that the contamination has reached groundwater, located about 100 m (330 ft) below ground surface (bgs) in this area. Initial characterization efforts indicated that the Tc-99 inventory is located mostly at a depth in the vadose zone of between about 30 and 70 m (98 and 230 ft) bgs. However, transport model predictions have indicated that the potential exists for this contamination to adversely affect groundwater in the future.

The active desiccation portion of the field test occurred over a 164-day period, ending on June 30, 2011. The injection and extraction wells were 12 m apart with multiple monitored locations surrounding the injection well. A clustered monitoring approach was used in the test, whereby a borehole (sensor borehole) containing sensors, gas-sampling ports, and electrical resistance tomography electrodes was placed nominally adjacent to a cased, unscreened well (logging well) that was used both to conduct neutron moisture logging and for application of cross-hole ground penetrating radar (GPR). Monitoring with the in situ sensors and geophysical techniques has been continued for the post-desiccation (rewetting) phase of the test.

The rate of moisture rewetting of the desiccated zones over time is a function of the hydraulic gradient, water relative permeability, and porous media unsaturated flow properties. Rewetting data since the end of active desiccation are consistent with expectations based on related laboratory data and numerical simulation analyses. Analysis of the data demonstrate that water advection from relatively wetter zones to dryer zones has occurred. For the zone of most extensive desiccation, nominally between 14 m and 16 m bgs, water advection has occurred primarily vertically downward from the wetter lower-permeability sediments at depths shallower than 14 m bgs. These shallower depth sediments were not

significantly dried during desiccation operations. At many locations, a substantial portion of the water removed by desiccation has returned to the desiccation zone over the 3-year rewetting monitoring period. This relatively rapid rewetting was expected based on the moisture conditions within and adjacent to these locations. In the monitored zones showing the thickest vertical intervals of desiccation, rewetting increased the moisture content in the shallow portion of the desiccated zone, but other portions remained dry. To date, the rewetting data are consistent with expectations for desiccation test performance based on laboratory and numerical simulations. These data are important to provide confidence in the design process to scale-up desiccation from the small test-site scale to a larger scale with sufficient capacity to maintain dry conditions over long periods of time, thus helping to mitigate contaminant flux to groundwater.

Acknowledgments

This work was funded by the CH2M Hill Plateau Remediation Company as part of the Deep Vadose Zone Treatability Test activities for the Hanford Central Plateau. The monitoring effort was partially conducted by the Deep Vadose Zone–Applied Field Research Initiative at Pacific Northwest National Laboratory with funding for that part of the effort by the U.S. Department of Energy (DOE) Richland Operations Office. The Pacific Northwest National Laboratory is operated by Battelle Memorial Institute for the DOE under Contract DE-AC05-76RL01830.

1.0 Introduction

Although the depth of some inorganic and radionuclide contamination in the vadose zone at the Hanford Site is beyond the point where direct exposure pathways are relevant, remediation may still be required to protect groundwater (DOE/RL 2008a). However, remediation options for contamination deep in the vadose zone are limited by the physical and hydrogeologic properties of the vadose zone (Dresel et al. 2011). In response to the Tri-Party Agreement Milestone M-015-50, the *Deep Vadose Treatability Test Plan for the Hanford Central Plateau* was issued in March 2008 (DOE/RL 2008a). This plan is for a treatability test program to evaluate potential deep vadose zone remedies for groundwater protection. Accordingly, the field test of vadose zone desiccation was conducted (Truex et al. 2012a and b, 2013a) and continued post-desiccation monitoring is now under way as part of this effort, with monitoring documented over time in interim data summary reports (Truex et al. 2013b).

The Hanford Site 200-BC-1 Operable Unit (the BC Cribs and Trenches Area) has subsurface conditions that serve as an example of vadose zone contamination issues and was selected as the location of the desiccation field test site. This waste site contains 26 cribs and trenches that received about 110 million liters of liquid waste, primarily in the mid-1950s. The waste contained about 410 curies of technetium-99 (Tc-99) (Corbin et al. 2005). There is no evidence that the contamination has reached groundwater, located about 100 m below ground surface (bgs) in this area. Initial characterization efforts indicated that the Tc-99 inventory is located mostly at a depth in the vadose zone of between about 30 and 70 m bgs. However, transport model predictions have indicated that the potential exists for this contamination to adversely affect groundwater in the future (Ward et al. 2004). The groundwater contaminant concentrations that can result from vadose zone contamination are a function of the rate of contaminant movement through the vadose zone. For remediation, contaminant discharge from the vadose zone to the groundwater must be maintained at a magnitude low enough to achieve groundwater protection goals.

Desiccation of a portion of the vadose zone, in conjunction with a surface infiltration barrier, has the potential to minimize migration of deep vadose zone contaminants towards the water table (Truex et al. 2011). To apply desiccation, a dry gas is injected into the subsurface. The dry gas evaporates water from the porous medium until the gas reaches 100% relative humidity, after which the gas can no longer evaporate water. Evaporation can remove pore water and may result in very low moisture contents and decreased water relative permeability in the desiccated zone (Ward et al. 2008; Oostrom et al. 2009, 2012a and b; Truex et al. 2011, 2012a and b, 2013a and b). Because of these desiccation-induced changes, the future rate of movement of moisture and contaminants through this zone is decreased.

Laboratory and modeling studies have been conducted to study desiccation and provide a technical basis for its use as a potential remedy (Truex et al. 2011; Ward et al. 2008; Oostrom et al. 2009, 2011, 2012a and b). In these studies, the overall performance of desiccation in limiting water and contaminant flux through the vadose zone to the groundwater was shown to be a function of the final moisture content in the desiccated zone, contaminant concentration, sediment properties, size of the desiccated zone, the hydraulic properties and conditions in surrounding subsurface zones, and the net surface recharge rate. In the laboratory, desiccation was shown to be capable of reducing the moisture content to below the residual moisture content of the porous medium (Truex et al. 2011; Ward et al. 2008; Oostrom et al. 2009). Data from the field test of desiccation also demonstrated reduction of moisture content to below

Soil Desiccation Test Site and Depiction of Subsurface Gas Flow

the residual moisture content of the porous medium in some locations near the dry-gas injection well (Truex et al. 2012a and b, 2013a). However, the desiccation during the field test varied as a function of subsurface properties, flow patterns of the dry gas, and time, producing a range of moisture content reductions throughout the monitored portion of the test site.

After a portion of the vadose zone is desiccated, rewetting of this zone can occur by vapor- and aqueous-phase moisture transport.

The timescale of rewetting impacts

the overall performance of desiccation in minimizing contaminant flux to the groundwater. Truex et al. (2011) examined rewetting of desiccated zones in the laboratory and found that vapor-phase rewetting from adjacent humid soil gas, in the absence of advective soil gas movement, occurs slowly by diffusion of water vapor and increases the moisture content of desiccated porous medium to a limited extent, nominally to near the residual moisture content for the porous medium. The aqueous-phase rewetting rate was found to be a function of the relative aqueous-phase permeability of the porous medium and hydraulic capillary pressure gradients.

This report describes and interprets the third year of post-desiccation monitoring conducted at the field test site, extending the information about rewetting processes and rates presented in the initial field treatability test documents (Truex et al. 2012a and b, 2013a) and the previous post-desiccation interim data summary (Truex et al. 2013b). This is the second interim report including about three years of post-desiccation monitoring data out of the five years of post-desiccation monitoring specified in the field test plan (DOE/RL 2010b). Section 2.0 provides a summary of the results of active desiccation. The monitoring approach is described in Section 3.0, followed by a presentation of the post-desiccation monitoring results in Section 4.0. Section 5.0 presents conclusions from the post-desiccation data collected to date.

2.0 Summary of Active Desiccation Results

The objectives outlined in the field test plan (DOE/RL 2010b) associated with active desiccation were successfully addressed through the field testing and associated laboratory and modeling efforts conducted as part of the treatability test. In the field test, a portion of the subsurface was desiccated, creating conditions that reduce the rate of moisture and contaminant movement toward the groundwater. A design basis to apply desiccation for vadose zone remediation was developed and is available for use in subsequent feasibility and remedial design efforts (Truex et al. 2012a).

The distribution, rate, and extent of desiccation observed in the field were affected by subsurface heterogeneity in geologic materials. A more rapid reduction in moisture content was observed for higher permeability materials. However, the moisture content in initially wetter, lower-permeability zones of limited extent was also reduced over time. Field test results were consistent with expectations based on previous laboratory and modeling efforts that investigated aspects of the desiccation process. Note that the field test targeted desiccation in a portion of the subsurface with significant contrasts in permeability to allow evaluation of desiccation performance across multiple types of subsurface conditions. Full-scale application of desiccation would seek target depth intervals for dry gas injection that enable creation of thick desiccated zones and would avoid zones where injected gas flow would be minimal.

The test results and related laboratory and modeling efforts provide information to guide design and implementation of desiccation. Desiccation observed in the field test was consistent with design calculations and simulations based on the water-holding capacity of the injected gas. In addition, the distribution of desiccated zones met expectations; higher permeability zones dried first, followed by expansion of desiccation into lower-permeability zones over time. Analysis of data and use of numerical simulations indicate that full-scale designs can be made more cost effective than the design of the field test (which was designed to collect specific data, not as a full-scale remediation) by using ambient air as the injected dry gas and by using an injection-only design (i.e., no extraction well).

Selected results from pre-desiccation characterization and active desiccation are incorporated into this report to provide a starting point and context for interpreting post-desiccation data. Detailed descriptions of pre-desiccation data and the active desiccation test results are available in the following reports and articles.

3.0 Post-Desiccation Monitoring Approach

The post-desiccation monitoring approach featured an experimental design and procedures developed to meet the test objectives presented in the field test plan (DOE 2010b).

3.1 Objectives

The objectives relevant to the post-desiccation monitoring phase of the field test are as follows:

- Desiccation Field Test Performance: Demonstrate field-scale desiccation for targeted areas within the vadose zone.
 - After desiccation is completed, determine the rate of change in soil moisture for the desiccated zone.
 - Determine the best types of instrumentation for monitoring key subsurface and operational parameters to provide feedback to operations and evaluate long-term effectiveness.

3.2 Experimental Design and Procedures

The experimental design and procedures are described by Truex et al. (2012a) and are briefly summarized below to provide context for the post-desiccation monitoring effort.

3.2.1 Test Site Background

The field treatability test for desiccation was conducted in the Hanford Site 200-BC-1 Operable Unit, commonly referred to as the BC Cribs and Trenches Area (Figure 3.1). The site was selected for the field test because relatively high concentrations of mobile Tc-99 contamination and high moisture contents are present at relatively shallow depths, facilitating test operations, yet representing conditions found deeper in the vadose zone where desiccation could be considered as part of a remedy. For the test, the deep vadose zone was mimicked by covering the ground surface with an impermeable barrier to limit surface interaction with the test injection and extraction operations. The test area is located between adjacent waste disposal cribs where the subsurface was affected by lateral movement of crib discharges in the subsurface but where drilling and other test operations could take place outside the hazardous footprint of the former disposal cribs. Figure 3.2 shows the vertical stratigraphy, technetium, and moisture distribution at the injection well location in relation to the well screen interval. Porous media grain-size variations in the test interval generally range from sands to loamy sands with some zones of silty sand and silt, similar to the porous media observed throughout the full depth interval.

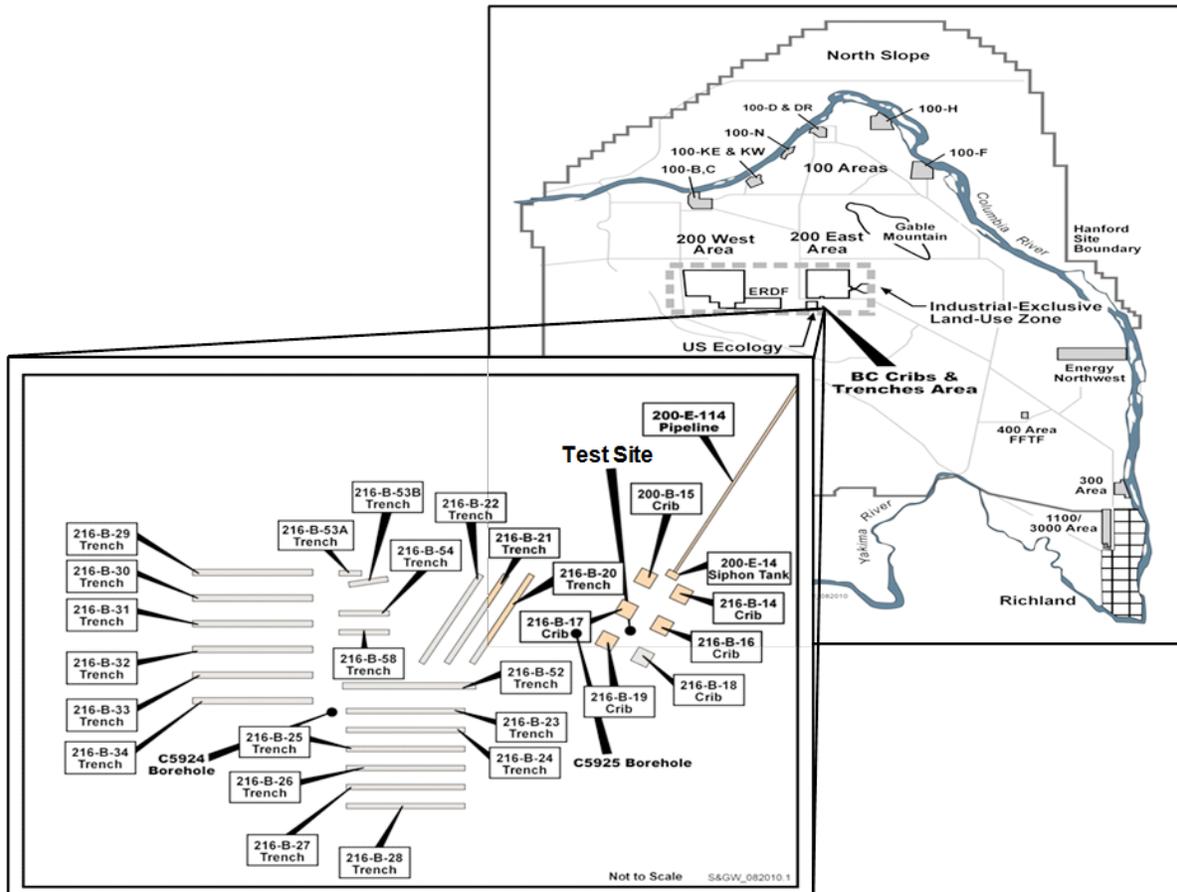

Figure 3.1. Test Site Location in the BC Cribs and Trenches Area (inset, 200-BC-1 Operable Unit) of the Hanford Site (map) (after DOE 2010b). Note that the test site is centered around borehole C5923 (coincident with the “Test Site” labeled on the figure), one of three characterization boreholes (C5923, C5924, C5925) from site investigation activities associated with electrical resistivity studies at the site (Serne et al. 2009).

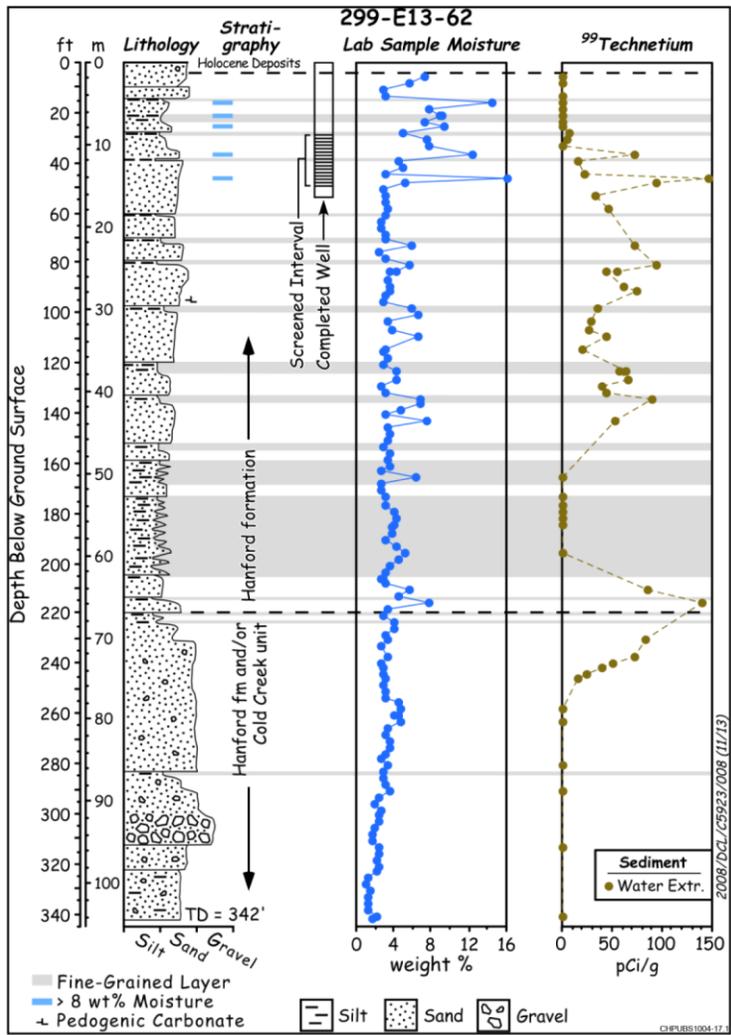

Figure 3.2. Injection Well Borehole Data and Screened Interval (after DOE 2010b)

Borehole data provides information about the vertical distribution of moisture and contaminant concentrations at the injection and extraction well locations of the field test site (e.g., Figure 3.3) (Serne et al. 2009; Um et al. 2009).

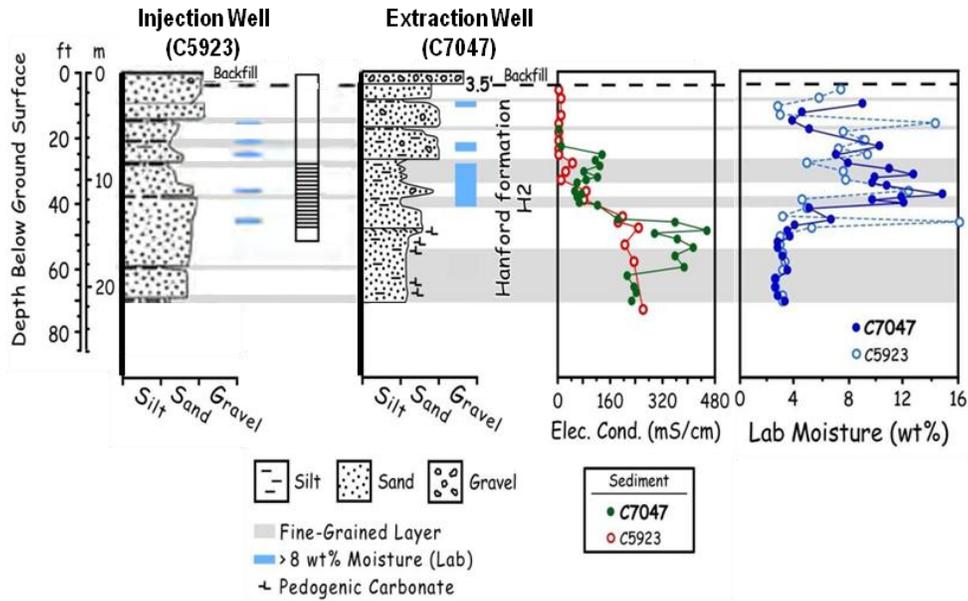

Figure 3.3. Injection and Extraction Well Borehole Initial Laboratory Moisture Content, Extracted Pore Water Electrical Conductivity, and Well Screened Interval (after DOE 2010a; Serne et al. 2008; Um et al. 2009)

3.2.2 Test Layout, Operations, and Equipment

The desiccation technology relies on removal of water from a portion of the subsurface such that the resultant low moisture conditions inhibit downward movement of water and dissolved contaminants. Implementation requires establishing sufficiently dry conditions within the targeted zone to effectively inhibit downward water transport. Nominally, the targeted zone would need to extend laterally across the portion of the vadose zone where contaminants have the potential to move downward at a flux that will affect groundwater above the remediation objective groundwater concentration. Thus, the experimental design was developed to evaluate the process of establishing a desiccated zone that extends laterally away from a dry gas injection well within a specific depth interval of the vadose zone. To obtain this type of desiccation zone, the field test design used a dipole configuration with injection of nitrogen and extraction of soil gas through wells screened in a target depth interval to favor soil gas flow within this interval and within a defined monitoring zone (Figure 3.4).

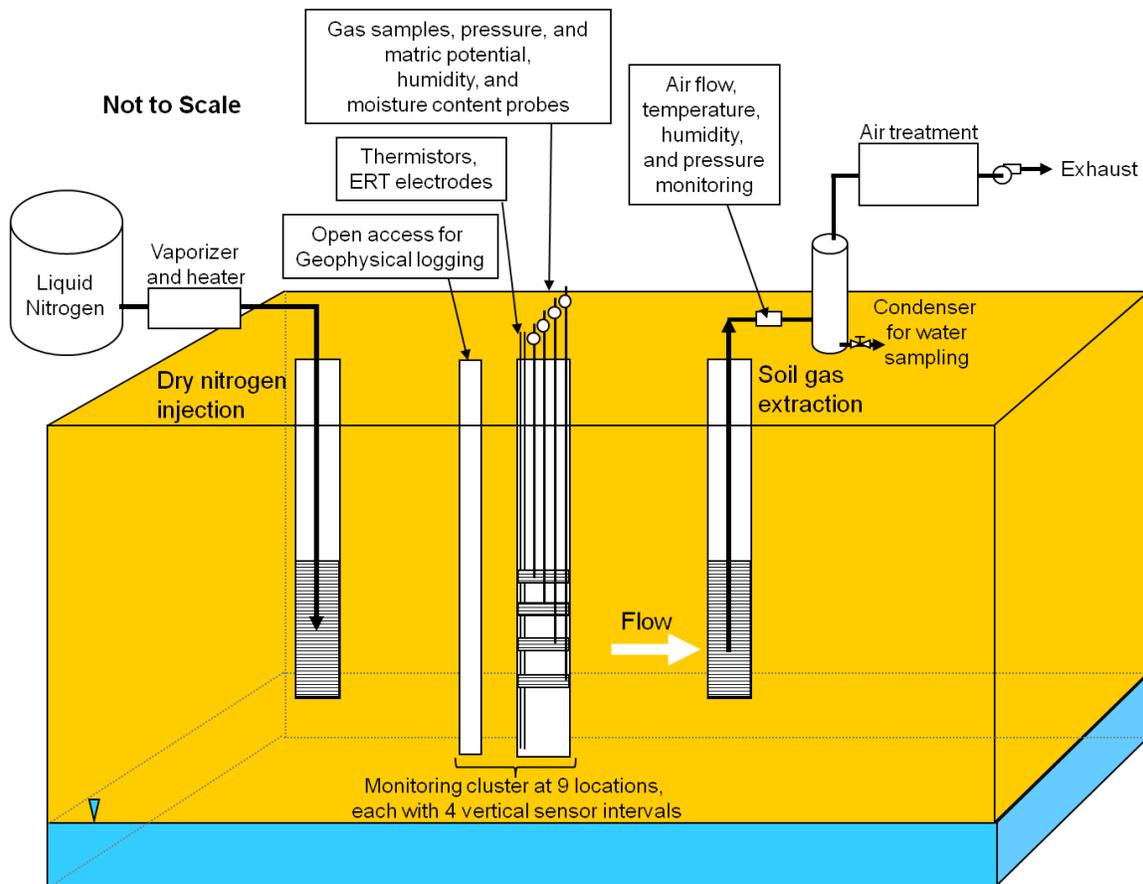

Figure 3.4. Basic Components of the Desiccation Field Test System

The general operational and in situ monitoring strategy is depicted in Figure 3.4. Dry nitrogen gas produced from liquid nitrogen tankers was injected at a controlled temperature of 20°C into a screened interval from 9.1 to 15.2 m (30 to 50 ft) bgs. Equipment testing, including trial nitrogen gas injections and the initial tracer test, occurred between November 22 and December 6, 2010. The active desiccation portion of the field test occurred with nitrogen injection at a stable flow rate of 510 m³/h (300 cubic feet per minute [cfm]) from January 17, 2011, through June 30, 2011, (164 days) except during a 13-day interval from April 21 through May 4, 2011, when there was no injection. Extraction of soil gas from a well screened from 9.1 to 15.2 m (30 to 50 ft) bgs was maintained for the full test duration at a stable flow rate of 170 m³/h (100 cfm). Extracted soil gas was routed through a heat exchanger to condense water that was collected and periodically sampled. The injection and extraction wells were 12 m apart.

Operational data were collected during injection and extraction operations at the test site. Of these parameters, the injected gas flow rate and temperature are key drivers for desiccation. Dry nitrogen (relative humidity of zero) was used for the injection gas during the test (Table 3.1). Extraction parameters were also measured to define test conditions, but are not specifically related to the desiccation rate other than the impact on soil gas flow rates and patterns. Figure 3.5 shows the operational parameter data for injection gas flow and extraction flow rate over the duration of active desiccation. Injection gas temperature was held essentially constant at about 20°C.

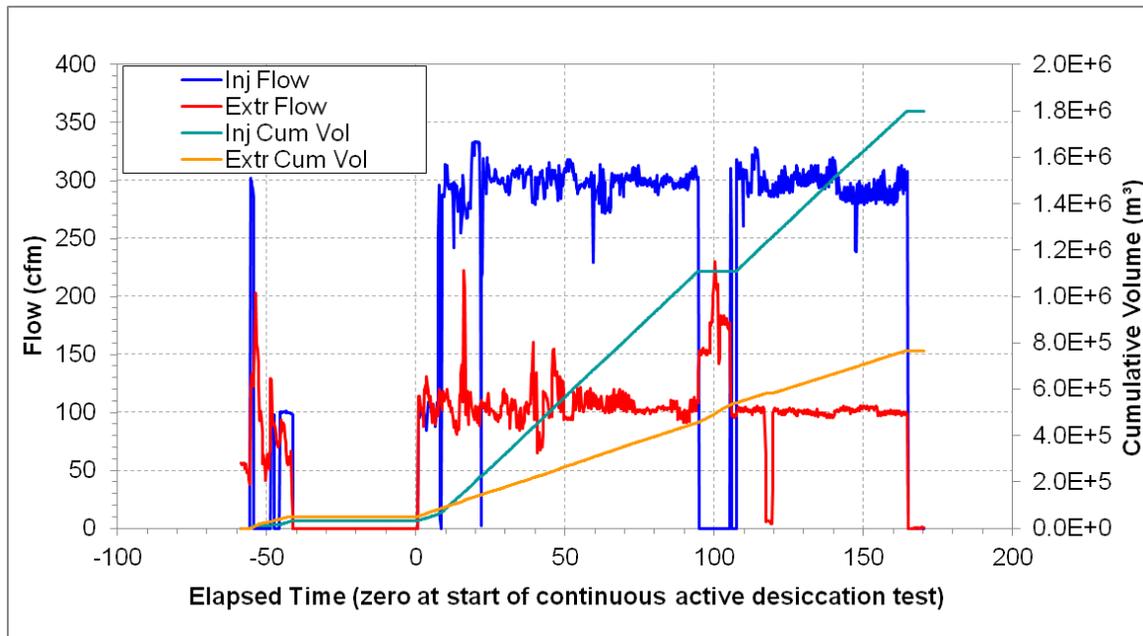

Figure 3.5. Flow Conditions and Cumulative Volumes for Field Test Operations

Figure 3.6 depicts the lateral layout of injection and extraction wells and the monitoring locations. Distances from the injection well to the monitoring locations are listed in Table 3.2. A 30-m by 45-m gas-impermeable membrane barrier was installed at the surface and centered over the well network. A clustered monitoring approach was used in the test whereby a borehole (sensor borehole) containing sensors, gas-sampling ports, and electrical resistance tomography electrodes was placed nominally adjacent to a cased, unscreened well (logging well) that was used to conduct neutron moisture logging and for application of cross-hole ground penetrating radar (GPR). Sensor boreholes contained four intervals of 100-mesh (>0.125 and <0.149 mm) Colorado sand (Colorado Silica, Colorado Springs, Colorado) separated by granular bentonite. Matric potential sensors, moisture content sensors, humidity sensors (sensors are described in Section 3.2.2.1), and porous polyethylene gas-sampling ports (model X-6081, Porex Technologies Corporation) were installed in each sand interval. The sand intervals were placed nominally at 9.5–10.1, 11–11.6, 12.5–13.1, and 14–14.6 m (31–33, 36–38, 41–43, and 46–48 ft) bgs to provide vertically discrete monitoring across the injection/extraction well screen interval. The boreholes contained thermistor temperature sensors every 0.6 m (2 ft) from 3 to 21.3 m (10 to 70 ft) bgs

and electrical resistivity electrodes every 1.5 m (5 ft) within the bentonite intervals of the borehole fill material from 3 to 21.3 m (10 to 70 ft) bgs. Electrical resistivity tomography (ERT) electrodes were placed within the bentonite zones with tubing installed to enable the addition of water around each electrode to locally hydrate the bentonite and maintain effective coupling between the electrode and the subsurface. Electrical connectivity was checked periodically during the test and water added when necessary to maintain adequate coupling. Logging wells, which provided access for neutron moisture logging and cross-hole GPR, extended to 21.3 m (70 ft) bgs with a 2-in. polyvinyl chloride casing (plugged at the bottom) in a 4-in.-diameter borehole and 100-mesh Colorado sand in the annular space.

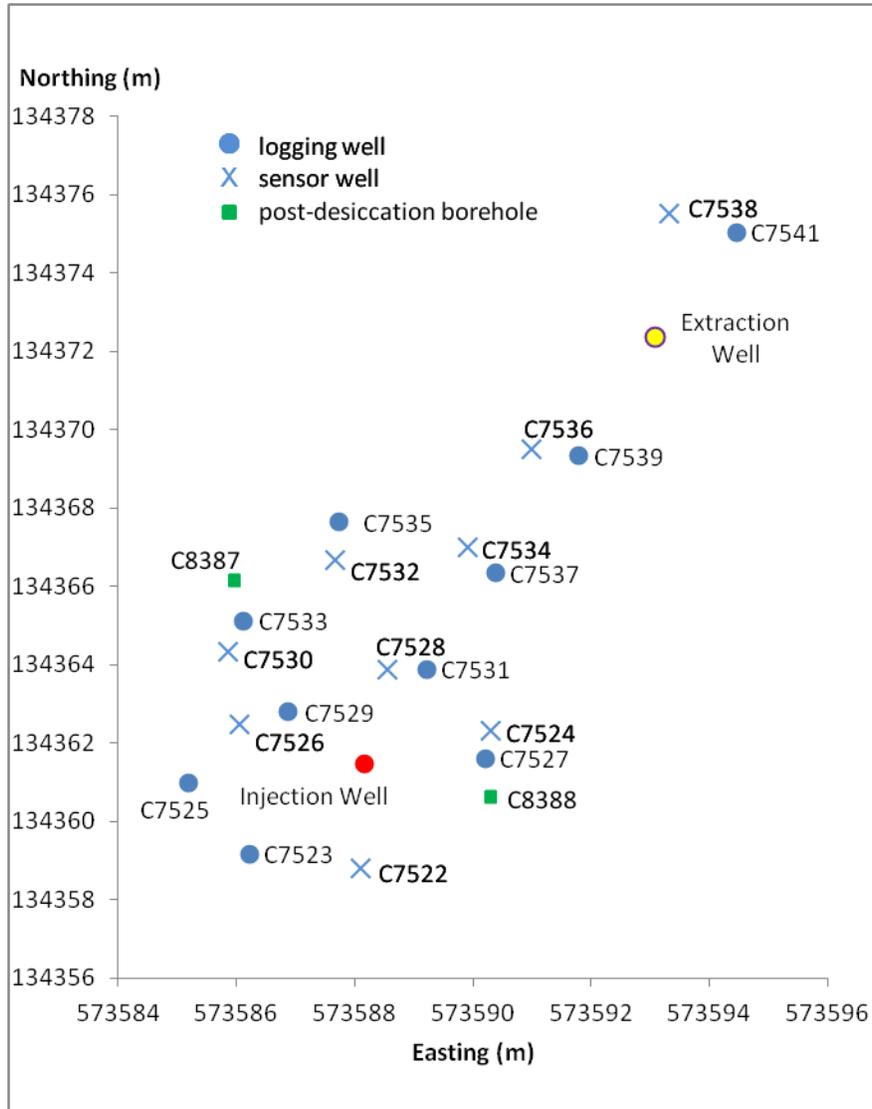

Figure 3.6. Location of Test Site Logging Wells, Sensor Boreholes, and Post-Desiccation Boreholes for Collection of Sediment Samples. A background sensor borehole (C7540, not shown) was 15 m southeast from the injection well.

Table 3.2. Field Site Monitoring Locations

| Monitoring Location | Distance from Injection Well (m) |
|---------------------|----------------------------------|
| C7526-S | 2.33 |
| C7529-L | 1.85 |
| C7524-S | 2.28 |
| C7527-L | 2.04 |
| C7528-S | 2.43 |
| C7531-L | 2.62 |
| C7522-S | 2.68 |
| C7523-L | 3.02 |
| C7525-L | 3.02 |
| C7530-S | 3.67 |
| C7533-L | 4.18 |
| C7534-S | 5.79 |
| C7537-L | 5.34 |
| C7532-S | 5.22 |
| C7535-L | 6.18 |
| C7536-S | 8.49 |
| C7539-L | 8.64 |
| C7538-S | 14.96 |
| C7541-L | 14.94 |

An “S” designation is for boreholes that contained in situ sensors. An “L” designation is for cased wells that were used for logging access.

3.2.2.1 Borehole Sensor Descriptions

Thermistors (USP8242 encapsulated, negative temperature coefficient thermistors, U.S. Sensor, Orange, California) were used to monitor temperature. To achieve accurate temperature measurements over the range of interest, a fifth-order polynomial was used to relate resistance to temperature for each of the thermistors used in the field test. The manufacturer’s calibration relationship was verified for a subset of the thermistors in a precision water bath spanning a 0°C–40°C temperature range, with measured accuracies better than 0.07°C. Temperatures were logged continuously (10-min intervals) at each thermistor. In addition to providing important information concerning desiccation progress, the temperature field data are also used to correct the ERT-derived electrical conductivity to a standard temperature prior to using the ERT data for estimating volumetric water content.

Matric potential data were collected using Heat Dissipation Unit (HDU) sensors (229-L HDU, Campbell Scientific, Inc., Logan, Utah) to indirectly determine the air-water capillary pressure. A 50-mA current excitation module was used to supply current to the HDU sensors. The HDU temperature was measured prior to heating and again at 1 s and 30 s after the onset of heating; these values were used to compute the associated matric potential (Ostrom et al. 2012a). The measurement range of the units is typically from -0.01 to -2.5 MPa (-0.1 to -25 bar) with an accuracy of 1 kPa (Flint et al. 2002). The procedure described by Bilskie et al. (2007) was used for HDU calibration, which simplifies the extended procedure presented by Flint et al. (2002) by only requiring calibration data in the range up to -70 kPa.

Once installed, the sand zones containing the HDU sensors were allowed to equilibrate with the conditions in the native formation before the injection operations were initiated.

Soil gas relative humidity was monitored using a CS215 capacitive relative humidity and temperature sensor (Campbell Scientific, Inc., Logan, Utah) with the electronics integral to the unit. The signal excitation and measurement are all completed within the device, followed by a conversion to a digital signal that can be monitored remotely. The sensing element is housed within a sintered high-density polyethylene filter to protect it from impact and environmental conditions. Each humidity probe is factory calibrated and the accuracy of the device is 2% within the 10% to 90% relative humidity range and 4% from 0% to 100% relative humidity.

Borehole sensors also included Thermocouple Psychrometer (TCP) units (PST-55, Wescor Inc., Logan, Utah) and Dual-Probe Heat Pulse sensors (Specific Heat Sensors, East 30 Sensors, Pullman, Washington), but these sensors were not tracked during the rewetting period due to poor responses and sensor failures observed during the active desiccation phase (Truex et al. 2012a).

3.2.2.2 Neutron Moisture Logging Measurements

Neutron moisture logging was conducted using a CPN 503DR Hydroprobe (InstroTek Inc., Raleigh, North Carolina). Neutron probe measurements were acquired at depth increments of approximately 7.5 cm using a count time of 30 s and then converted to count ratio (C_R) by dividing each measurement by the standard count. For the desiccation field test, neutron probes were deployed periodically in wells at the site to collect neutron moisture logs with data at discrete depth intervals in the subsurface.

Neutron probe data were converted to volumetric moisture content using a site-specific relationship that was developed from core measurements of gravimetric moisture content and bulk density (full description provided by Truex et al. [2012a]). In summary, core samples were collected adjacent to logging location C7527 after the active desiccation phase of the test. Neutron moisture probe C_R data were plotted with corresponding post-desiccation laboratory-measured volumetric moisture content (computed using measured gravimetric moisture content and bulk density) from samples at the same depth, laterally within 0.9 m of the neutron logging well (Figure 3.7). Assuming that soil moisture content values are not substantially different at that lateral distance from the logging well, the laboratory data were used to establish a calibration for the neutron moisture probe data. Regression of volumetric moisture content (θ) (see Truex et al. 2012a) and C_R data for all core samples resulted in the relationship $\theta = 0.714C_R^2 - 0.1363C_R$, with a root mean square error of 0.015 for θ and a coefficient of determination of 0.93.

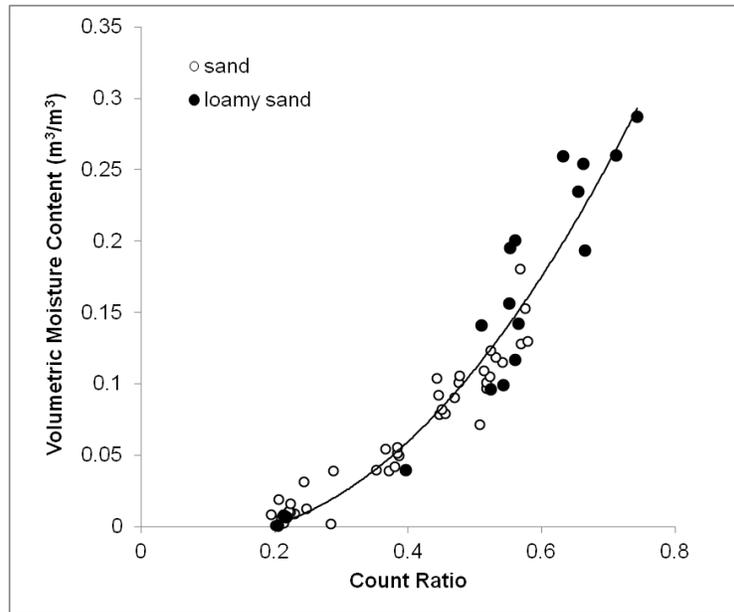

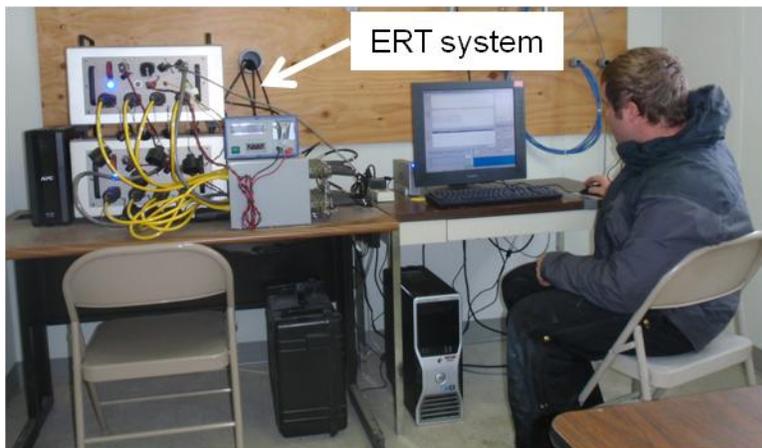

Figure 3.7. Calibration Relation for Neutron Moisture Probe Count Ratio Data and Corresponding Laboratory-Measured Volumetric Moisture Content

3.2.2.3 Cross-Hole Electrical Resistivity Measurements

ERT is a method of remotely imaging the electrical conductivity (EC) of the subsurface. Electrodes installed along the ground surface and/or within boreholes are used to strategically inject currents and measure the resulting potentials to produce a data set that is used to reconstruct the subsurface EC structure (Daily and Owen 1991; Johnson et al. 2010). With respect to soil desiccation, EC is a useful metric for characterizing the subsurface because it is governed by properties that influence gas flow, including soil texture and moisture content. EC is also a useful metric for monitoring desiccation because it is sensitive to moisture content and temperature (Slater and Lesmes 2002), the two primary properties altered during desiccation.

Control System for Electrical Resistivity Tomography

The ERT electrode array deployed in this study was first used to characterize pre-desiccation subsurface structure, providing important 3D information regarding permeability and likely gas flow pathways. During desiccation, the same array was used to image 3D changes in EC from background caused primarily by decreasing moisture content but also by evaporative cooling. ERT surveys were collected twice per day during the desiccation phase, and weekly during the post-desiccation phase.

The resulting changes in EC were temperature-corrected and converted to changes in moisture content using a site-specific, laboratory-validated relationship (Archie 1942). Results of pre-desiccation and desiccation ERT monitoring are provided by Truex et al. (2012a, 2013a).

For the previously reported pre-desiccation and active desiccation test phases and for the post-desiccation test phase reported herein, ERT data were collected using 99 electrodes—11 electrodes in each of the 9 sensor wells. Full forward and reciprocal measurements were collected to estimate data noise and quality, and each data set contained 6114 measurements after filtering. Measurements were collected using an 8-channel MPT DAS-1 impedance tomography system.¹ These data were inverted with isotropic regularization smoothing constraints on an unstructured tetrahedral mesh with 354,544 elements using the imaging software described by Johnson et al. (2010). The EC data collected from the ERT system provide a means to image changes in the volumetric moisture content over time in three dimensions.

3.2.2.4 Cross-Hole Ground Penetrating Radar Measurements

GPR methods are also commonly used to characterize or monitor subsurface moisture content. GPR systems consist of an impulse generator that repeatedly sends a particular voltage and frequency source to a transmitting antenna. Cross-hole GPR methods involve lowering a transmitter into a wellbore and measuring the energy with a receiving antenna that is lowered down another wellbore, and moving the transmitting and receiving antennae manually to different positions in the wellbores to facilitate transmission of the energy through a large fraction of the targeted area.

Soil electrical permittivity is strongly dependent on moisture content because of the large difference

Ground Penetrating Radar Data Collection Equipment

between water and bulk soil permittivity. The relative permittivity of water is approximately 80, compared to values between 3 and 7 for typical soil mineral components. The permittivity can be determined from the observed velocity of an electromagnetic pulse propagating through the soil matrix. Studies have demonstrated that GPR methods can effectively estimate subsurface moisture content using measured electromagnetic velocities (Hubbard et al. 1997; Van Overmeeren et al. 1997; Huisman et al. 2001). In general, the electromagnetic velocity depends on both the permittivity and conductivity; however, when the conductivity is sufficiently low (i.e., low-loss conditions), GPR-derived velocities can be used to accurately determine permittivity and therefore moisture content.

¹ <http://www.mpt3d.com/>.

At the desiccation site, cross-borehole GPR surveys were conducted with the transmitting and receiving antennae placed in separate boreholes to measure the electromagnetic velocity between boreholes. Using measurements acquired from antennae located at many different vertical positions within each borehole, a two-dimensional (2D) image of properties between boreholes can be produced (Jackson and Tweeton 1994). These images can provide information that can be interpreted with respect to the geologic structure and moisture content between boreholes (Binley et. al 2002; Day-Lewis et al. 2002). For the desiccation field test, 2D images of electromagnetic velocity were generated with GPR and converted to volumetric moisture content changes using an established petrophysical relationship assuming low-loss conditions (Topp and Ferré 2002; Evett 2005). At the desiccation site, the electrical conductivity varies between 0 and 0.250 S/m and the low-loss assumption is not valid at all locations. Thus, GPR data are analyzed and interpreted in conjunction with the subsurface EC data provided by the ERT system.

GPR data were collected with a PulseEKKO 100 using a 100-MHz borehole antennae (Sensors and Software, Inc. Missasauga, Ontario, Canada). Multiple offset gather surveys were periodically collected in a set of four logging well pairs (using locations C7523, C7531, C7537, C7539, and the injection well). From these data, 2D electromagnetic velocity images were constructed using MIGRATOM, a curved ray inversion software (Jackson and Tweeton 1994).

3.2.2.5 Data Collection System

Sensor data for the field test were collected using CR3000 data loggers (Campbell Scientific Inc., Logan, Utah). Data were continuously and automatically retrieved from the data loggers and stored on a Dell T3400 computer located at the field site. A Raven X cellular phone modem (Sierra Wireless, Richmond, British Columbia, Canada) was installed to allow for remote monitoring of the data acquisition system and data transfer.

3.2.3 Data Management

Data from sensors were maintained on both data loggers and an onsite computer and were backed up periodically to an office computer. Sensor data were imported to spreadsheets at least twice per month during active desiccation and every 6 months during the rewetting phase. The spreadsheets were used to convert raw sensor data to the required outputs, to plot results, and to serve as an additional data storage file for the plotted data. Manual test logs were maintained to document primary test events and for operations where no electronic sensor was available (e.g., condensate collection). The electronic and manual data are stored as part of project records and are documented in project reports.

4.0 Post-Desiccation Monitoring Results

The results of the field test are presented in the next two sections. Results from sensors and geophysical monitoring are presented in Section 4.1 and the data assessment with respect to the field test objectives is discussed in Section 4.2.

4.1 Field Data Summary

Post-desiccation monitoring was conducted to collect data to quantify the stability of the desiccated zone (i.e., the rate of rewetting) and to evaluate the field performance of monitoring instruments. The sections below present the data with respect to each of these basic field test elements.

4.1.1 Post-Desiccation Data

The three primary types of monitoring—in situ sensor monitoring, neutron moisture logging, and GPR surveying—for the rewetting period (July 2011 through August 2014) are discussed, respectively, in the sections below on sensor, neutron, and geophysical data.

4.1.1.1 Sensor Data

In situ sensor monitoring was continued without interruption from the time of the last data reported in the prior year interim report (Truex et al. 2013b). The figures below (Figure 4.1 through Figure 4.8) show the temperature, matric potential, and humidity responses for the sensor locations where a response was observed during active desiccation. For reference, note that elapsed times of 800 and 1000 days post-active desiccation equate to dates of Sep. 7, 2013 and Mar. 26, 2014, respectively.

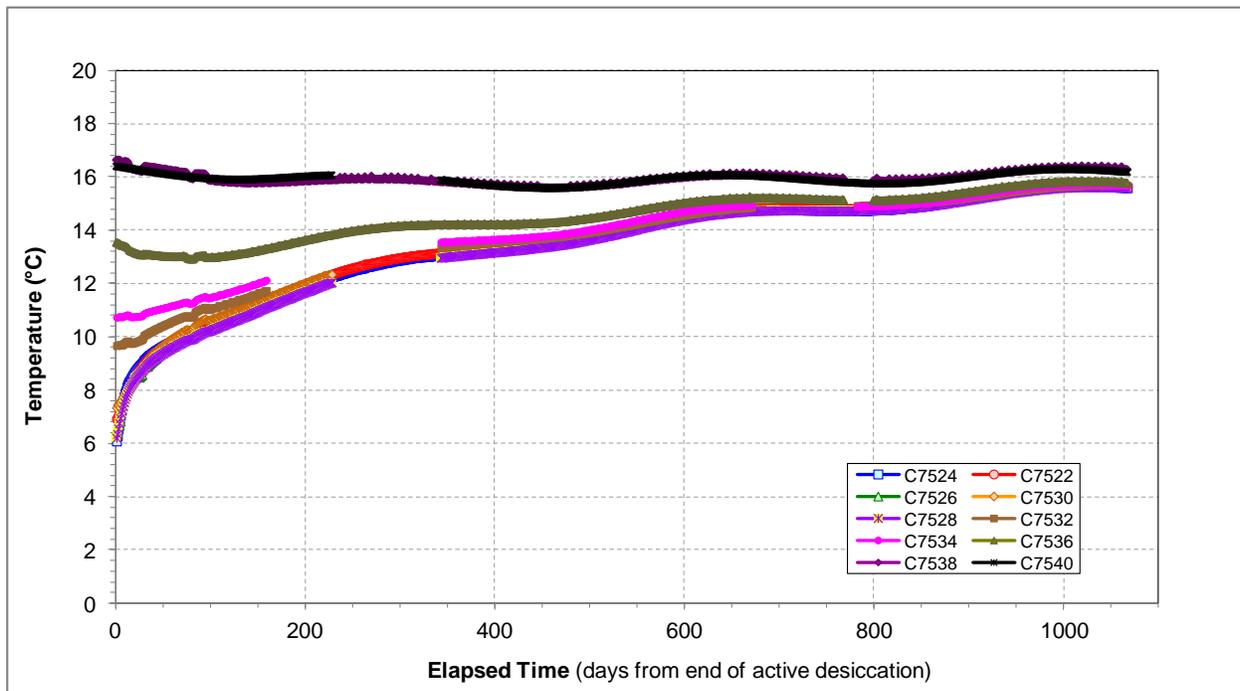

Figure 4.1. Post-Desiccation Temperature Response over Time for the Sensors at a Depth of 32.5 ft (9.9 m) bgs

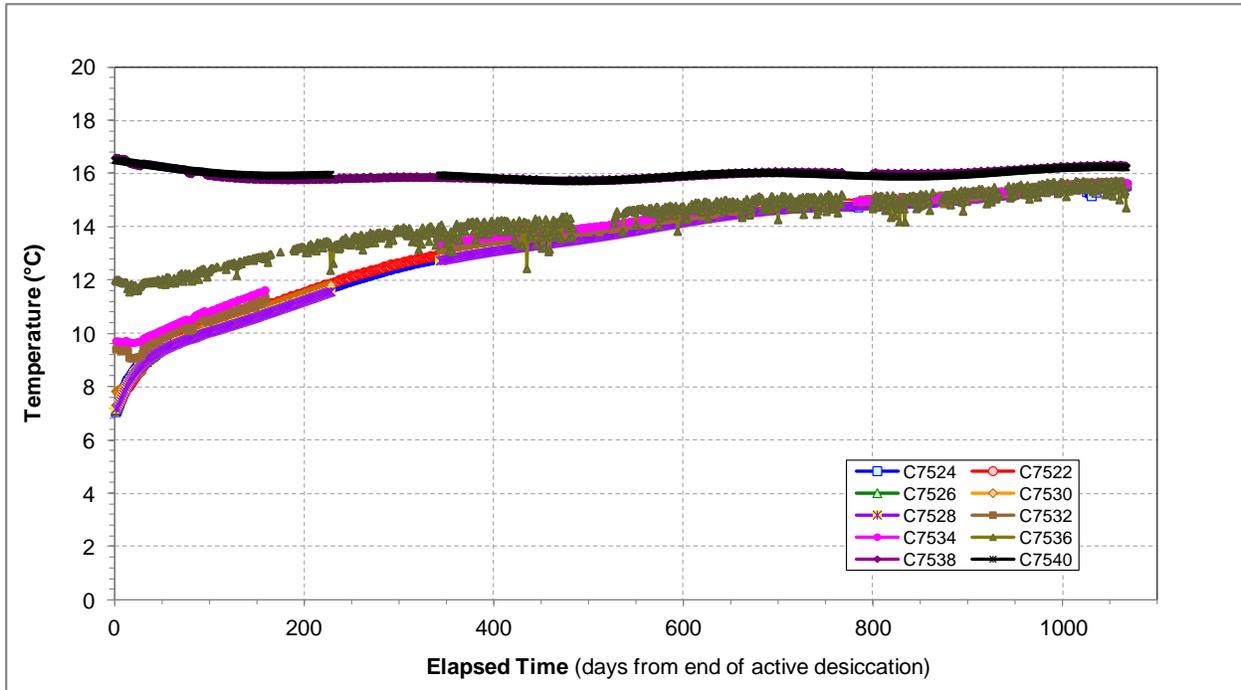

Figure 4.2. Post-Desiccation Temperature Response over Time for the Sensors at a Depth of 36.5 ft (11.1 m) bgs

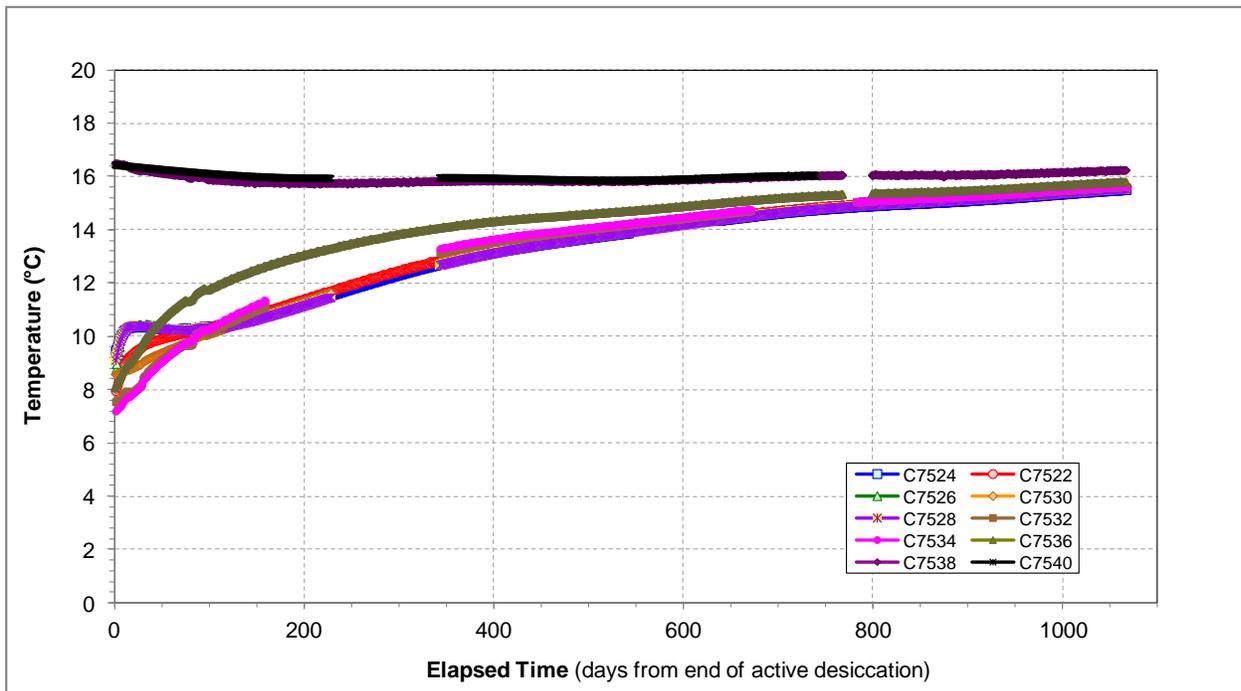

Figure 4.3. Post-Desiccation Temperature Response over Time for the Sensors at a Depth of 42.5 ft (13 m) bgs

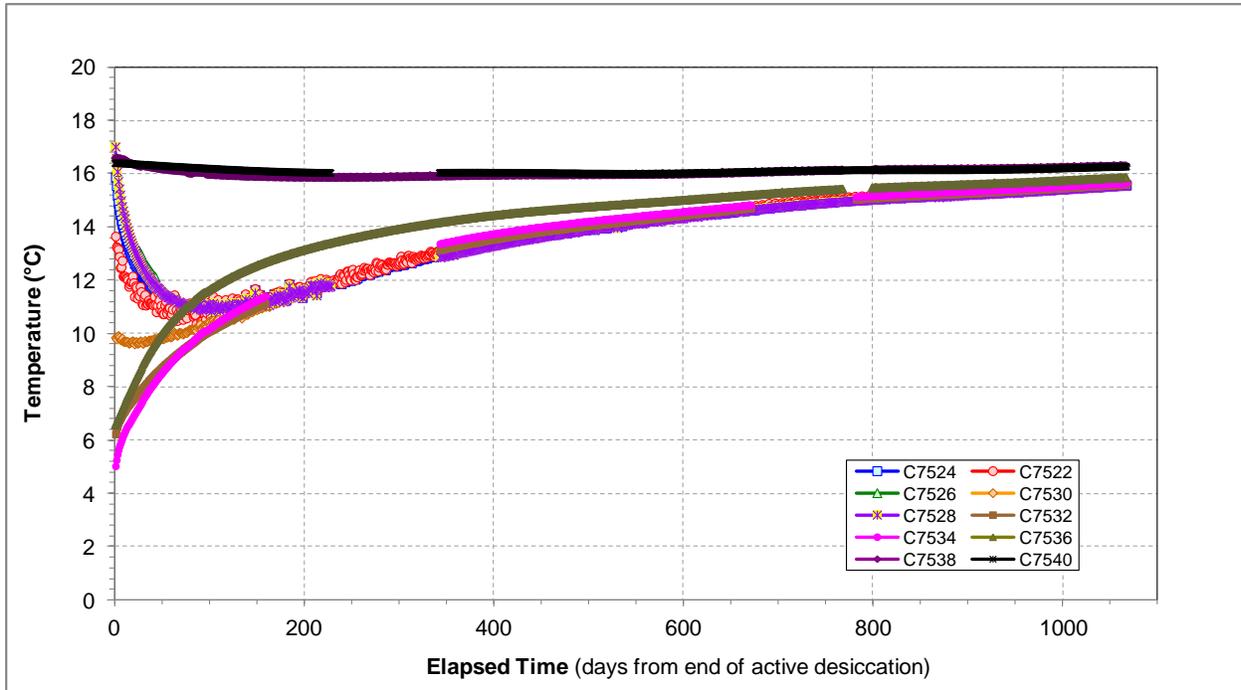

Figure 4.4. Post-Desiccation Temperature Response over Time for the Sensors at a Depth of 46.5 ft (14.2 m) bgs

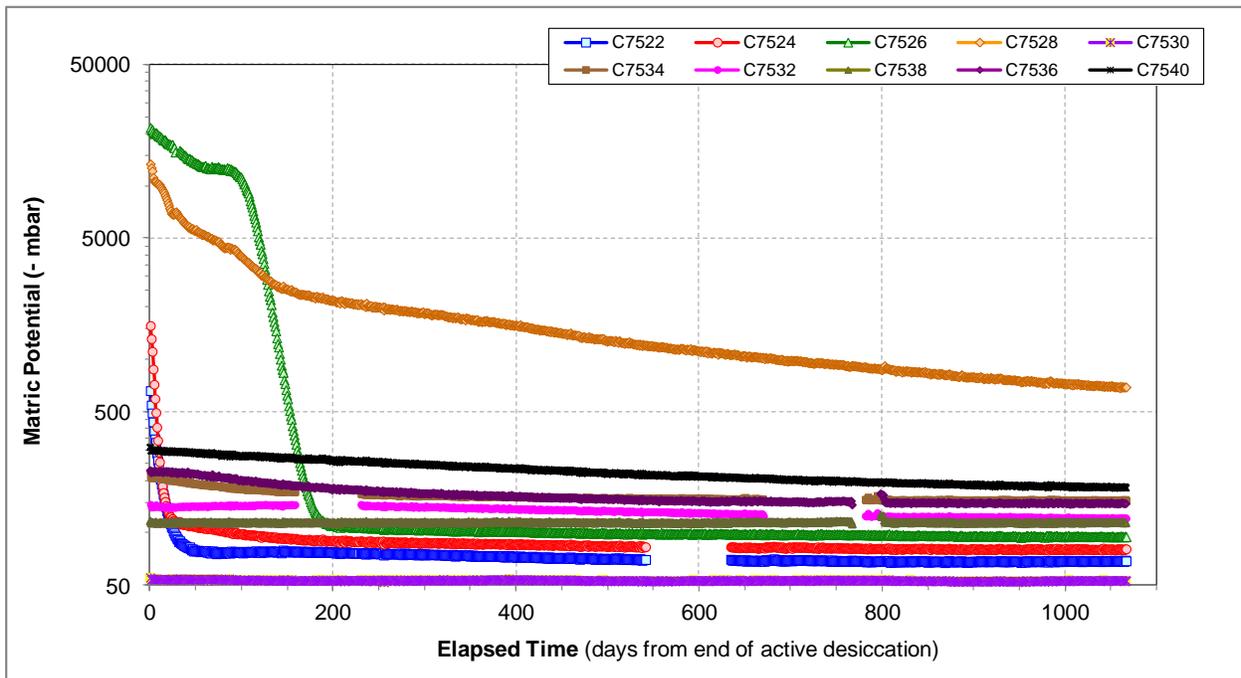

Figure 4.5. Post-Desiccation Heat Dissipation Unit (matric potential) Response over Time for the Sensors at a Depth of 42.5 ft (13 m) bgs. Note that the y-axis uses a logarithmic scale.

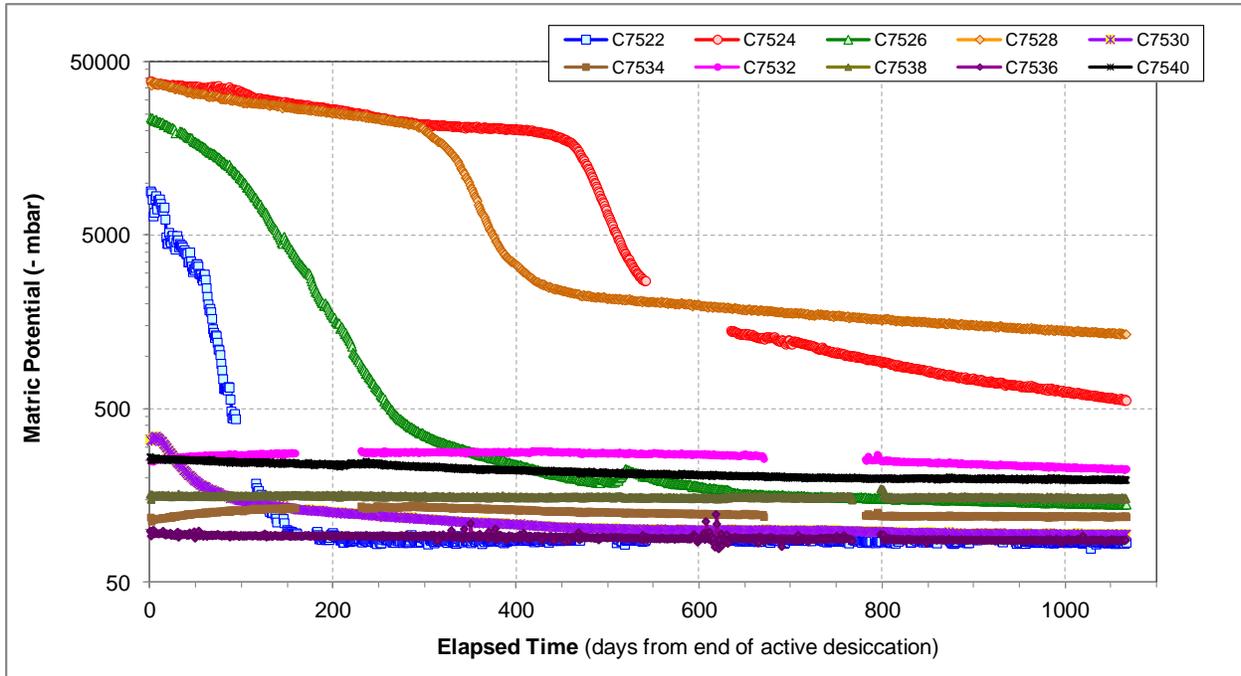

Figure 4.6. Post-Desiccation Heat Dissipation Unit (matric potential) Response over Time for the Sensors at a Depth of 47.5 ft (14.5 m) bgs. Note that the y-axis uses a logarithmic scale.

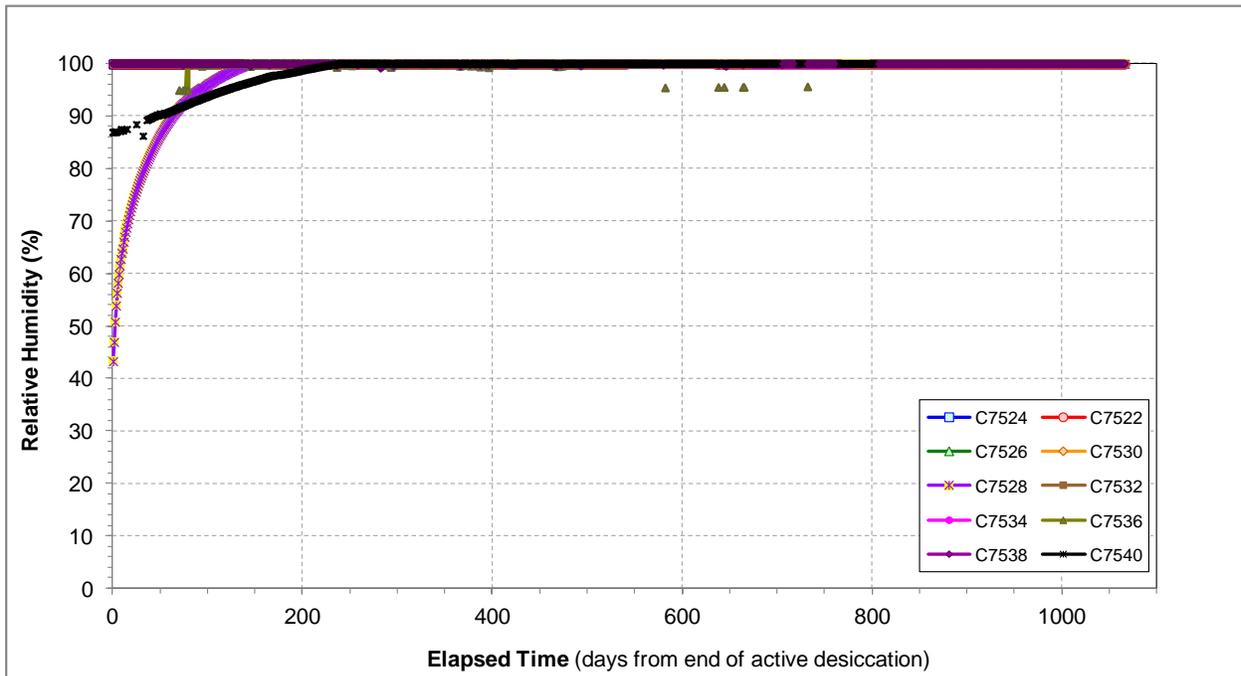

Figure 4.7. Post-Desiccation Relative Humidity Probe Response over Time for the Sensors at a Depth of 42.5 ft (13 m) bgs

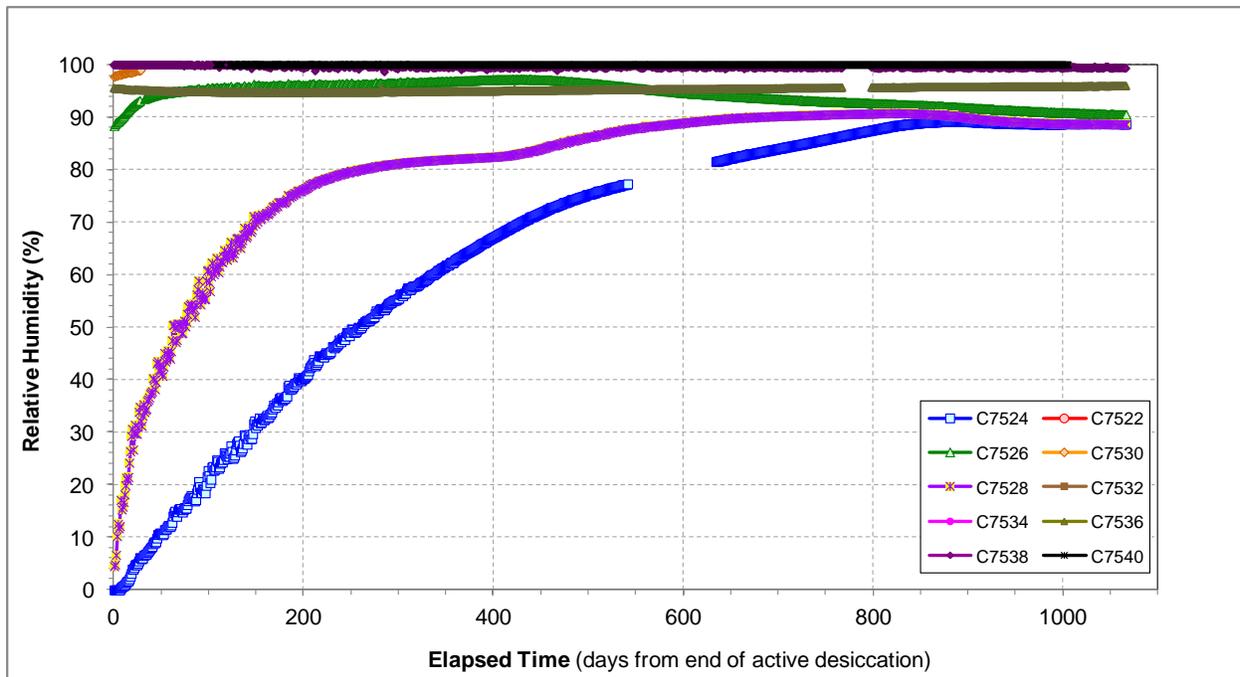

Figure 4.8. Post-Desiccation Relative Humidity Probe Response over Time for the Sensors at a Depth of 47.5 ft (14.5 m) bgs

Temperatures at the key depths of 32.5, 36.5, 42.5, and 46.5 ft bgs exhibited some variation within about the first 100 days after the end of active desiccation. For the depth of 46.5 ft (14.2 m) bgs, several locations (C7524, C7522, C7526, C7528, and, to some extent, C7530) had reached a state of higher temperatures during active desiccation as a result of drying to the point where evaporative cooling was no longer occurring. In contrast, evaporative cooling was still occurring at locations C7532, C7534, and C7536 for the 46.5 ft bgs depth, so those locations had low temperatures at the end of active desiccation operations. By about 100 days after active desiccation, temperatures at all locations for the 46.5 ft bgs depth were converging. Beyond these initial post-active desiccation variations, the temperatures at all four key depths have continued a gradual increase over time at locations near the injection well and are now less than 1°C different from temperatures at distant/background locations. All temperatures at these four depths are converging to approximately 16°C.

Several locations at depths of 42.5 and 47.5 ft (13 and 14.5 m) bgs had exhibited a significant change in matric potential (as measured with the heat dissipation unit sensors) to values between -5000 and -50000 mbar during active desiccation, indicating that significant drying occurred. After the end of active desiccation, the matric potential returned to nominally the pre-desiccation levels for most locations that had indicated drying. At a depth of 42.5 ft (13 m) bgs, the matric potential at locations C7522 and C7524 returned to around -75 to -100 mbar in a fairly short time frame (< 100 days) after the end of active desiccation. Matric potential at location C7526 for the 42.5 ft bgs depth shows a 100-day lag before a relatively rapid change from -13000 mbar to values near -100 mbar by 200 days after end of active desiccation. At location C7528 for the 42.5 ft depth, the matric potential indicated a more gradual rewetting, with conditions appearing to approach a stable state that is drier (at about -700 mbar) than pre-desiccation conditions (about -180 mbar). At the deeper 47.5 ft (14.5 m) locations, matric potential

indicated a somewhat slower rewetting. Location C7530, which was just beginning to show changes in matric potential indicative of drying at the end of active desiccation, quickly returned to pre-desiccation levels within about 100 days. Matric potential at C7522 for the 47.5 ft depth also had a relatively quick (within about 200 days) return to pre-desiccation matric potential. The return to pre-desiccation matric potential at the C7526 location for the 47.5 ft depth was delayed and more gradual than observed by the corresponding sensor at the 42.5 ft depth for that location. Matric potential at the 47.5 ft depth at the C7528 location exhibited a similar gradual rewetting and appears to be approaching a near-stable state with current readings at about -1400 mbar. At the C7524 location for the 47.5 ft depth, unlike the 42.5 ft depth, the matric potential showed rewetting after a much longer delay (about 450 days after the end of active desiccation) and a much more gradual rewetting that is currently near -550 mbar.

Several humidity sensors exhibited a transition to low relative humidity during active desiccation operation, indicating that drying was occurring. After the end of active desiccation, the lower relative humidity at a depth of 42.5 ft (13 m) for the C7528 location showed a relatively prompt (within about 150 days after the end of active desiccation) return to 100% relative humidity. While the humidity at a depth of 42.5 ft (13 m) for the C7540 location (background sensor) appeared to show a recovery to 100% relative humidity, this probe had previously shown essentially constant readings of about 85–90% since installation, so its readings are not considered accurate indications of humidity at that location. Humidity sensors at the 47.5 ft (14.5 m) depth for locations C7524 and C7528 have shown a much more gradual return to high humidity values. Since about 800 days after the end of active desiccation, these two sensors appear to have stabilized at around 90% relative humidity. At the C7526 location for the 47.5 ft (14.5 m) depth, moderate decreases in humidity were observed near the end of the active desiccation period. The humidity quickly rebounded at this location, although the humidity values have drifted over time, showing a decrease to about 90% relative humidity in the most recent readings. Several of the humidity probes both during and after active desiccation have shown readings below 100% relative humidity when it was expected that the relative humidity should be 100%. Thus, it is unclear whether these readings are accurate.

4.1.1.2 Neutron Data

Vertical profiles from neutron moisture logging events conducted pre-desiccation, just after active desiccation, and for three years of annual surveys after desiccation are plotted in the following figures (Figure 4.9 through Figure 4.15) to depict the relative rewetting that has occurred during this time frame. These data show a clear progression of rewetting, especially for thin desiccated zones adjacent to wetter zones. At the C7527 and C7529 monitoring locations, the thicker desiccated zones have shown the least rewetting. These thicker desiccated zones were areas of high injected air flow due to the presence of coarser, lower-moisture content sediments. While relatively wet sediments are present above these zones, the sediments below are also relatively coarse and dry. Therefore, rewetting of these zones has primarily occurred from above. Plots containing all of the neutron surveys that have been conducted (pre-desiccation, July 2011, August 2011, September 2011, December 2011, February 2012, May 2013, August 2013, March 2014, and August 2014) are included in Appendix A.

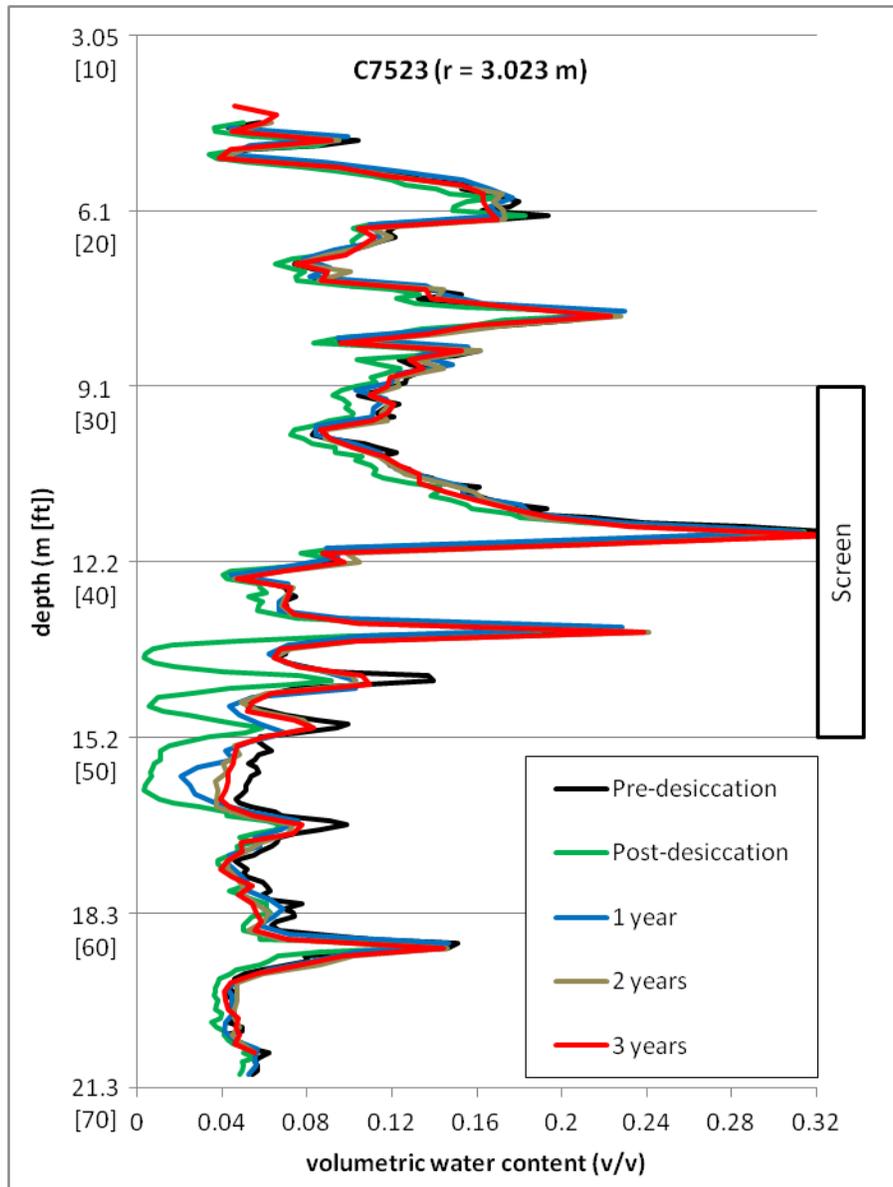

Figure 4.9. Neutron Moisture Probe Response over Time for Location C7523 (3.023 m from injection well). The pre-desiccation data are from a logging event in December 2010, prior to the continuous active desiccation period. Other data are for logging events after active desiccation ended.

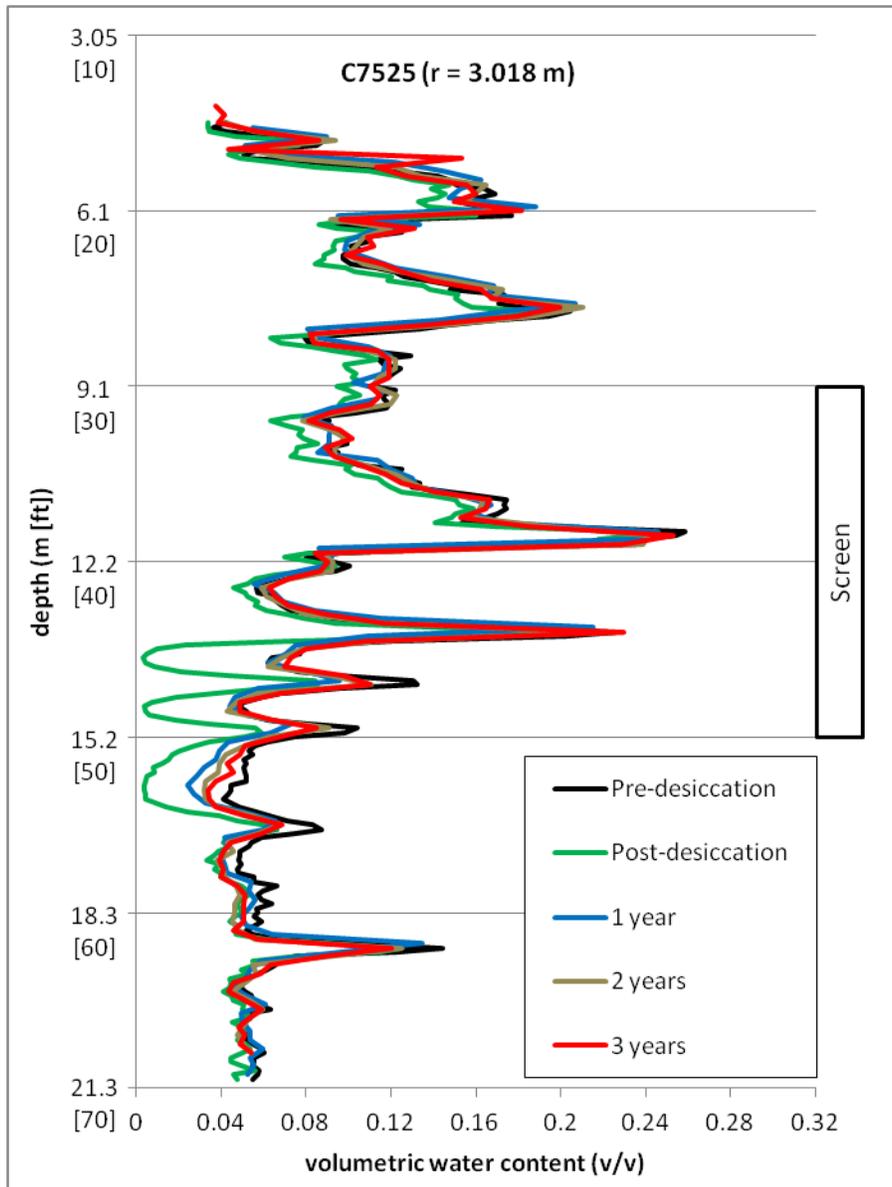

Figure 4.10. Neutron Moisture Probe Response over Time for Location C7525 (3.018 m from injection well). The pre-desiccation data are from a logging event in December 2010, prior to the continuous active desiccation period. Other data are for logging events after active desiccation ended.

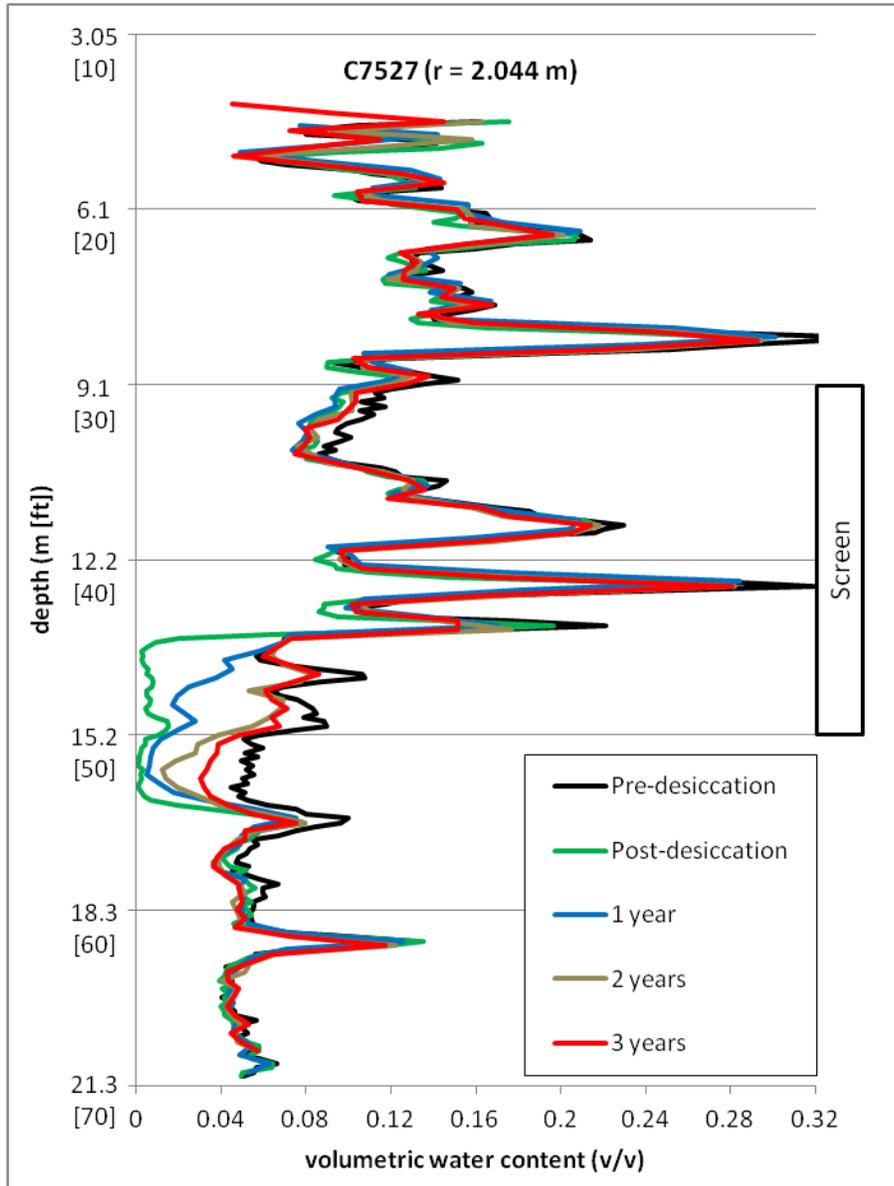

Figure 4.11. Neutron Moisture Probe Response over Time for Location C7527 (2.044 m from injection well). The pre-desiccation data are from a logging event in December 2010, prior to the continuous active desiccation period. Other data are for logging events after active desiccation ended.

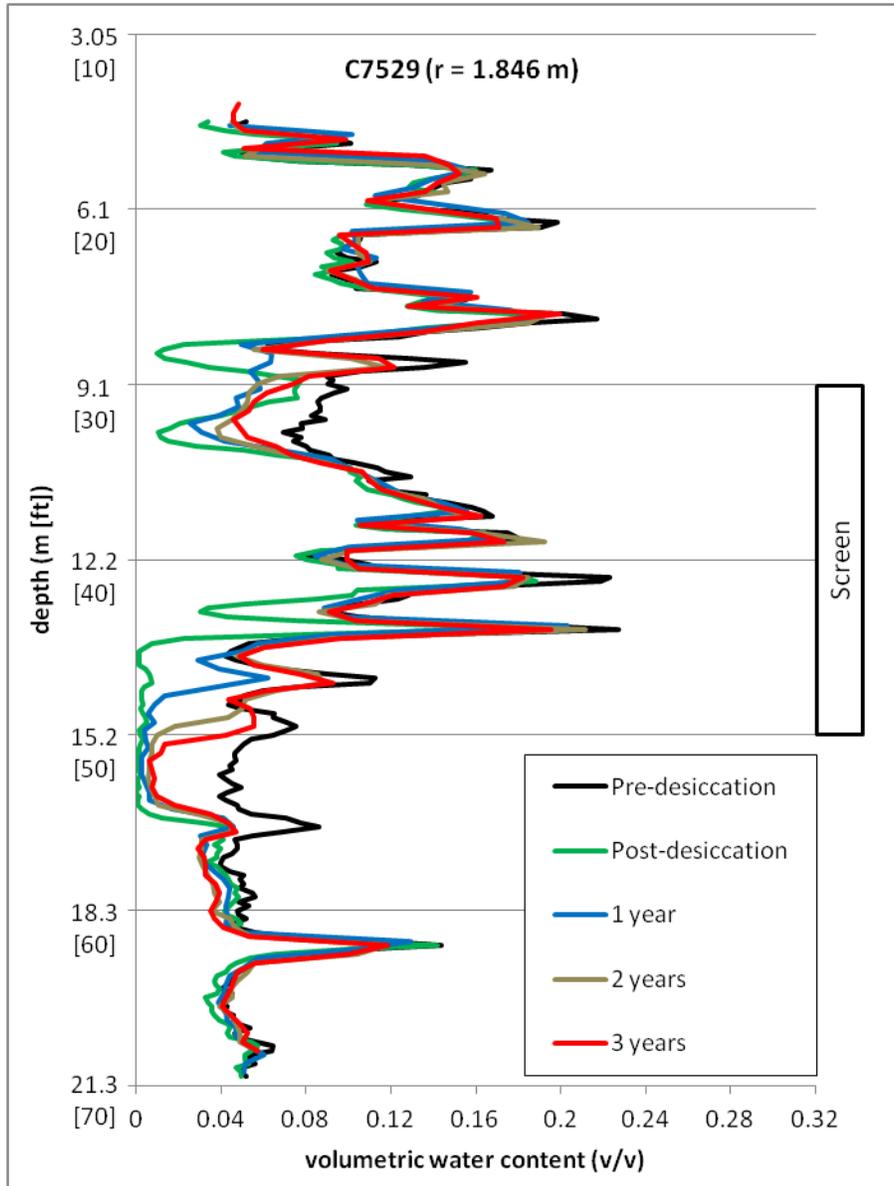

Figure 4.12. Neutron Moisture Probe Response over Time for Location C7529 (1.846 m from injection well). The pre-desiccation data are from a logging event in December 2010, prior to the continuous active desiccation period. Other data are for logging events after active desiccation ended.

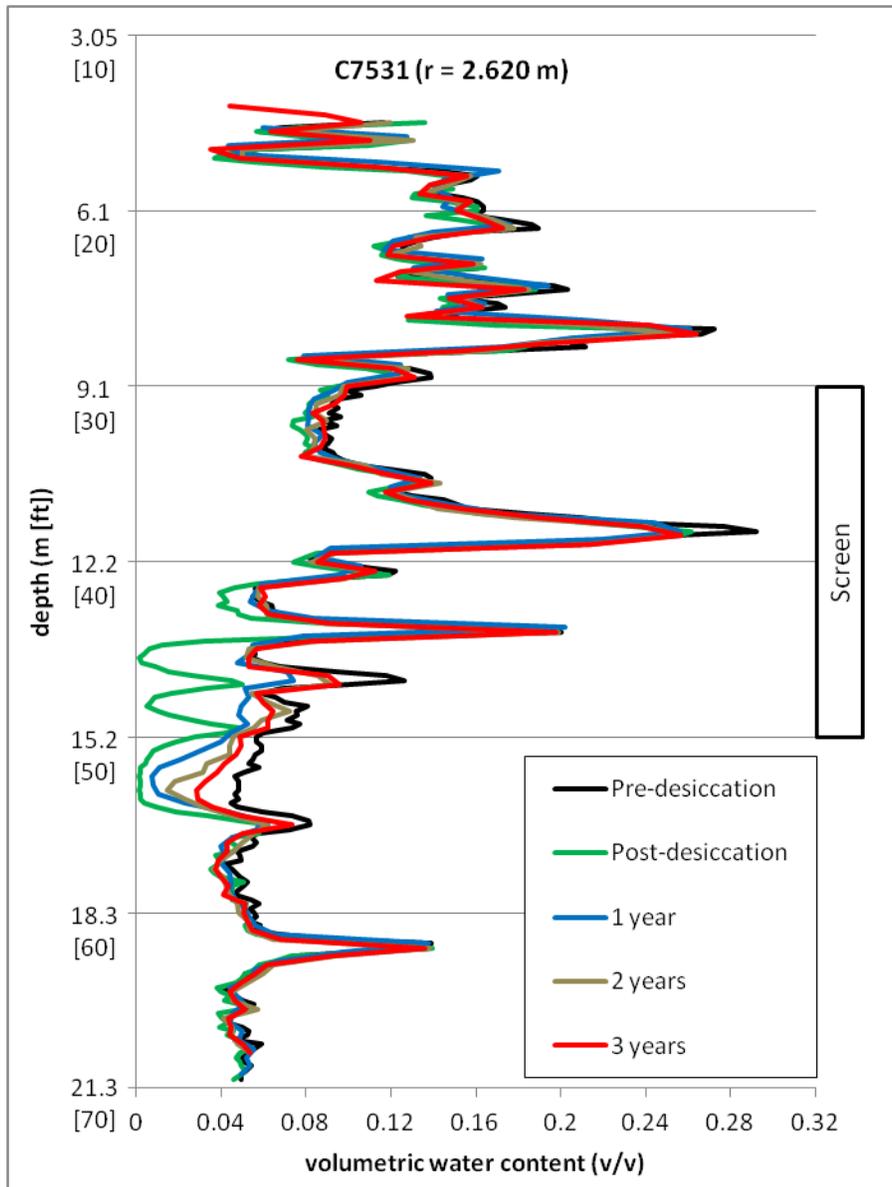

Figure 4.13. Neutron Moisture Probe Response over Time for Location C7531 (2.620 m from injection well). The pre-desiccation data are from a logging event in December 2010, prior to the continuous active desiccation period. Other data are for logging events after active desiccation ended.

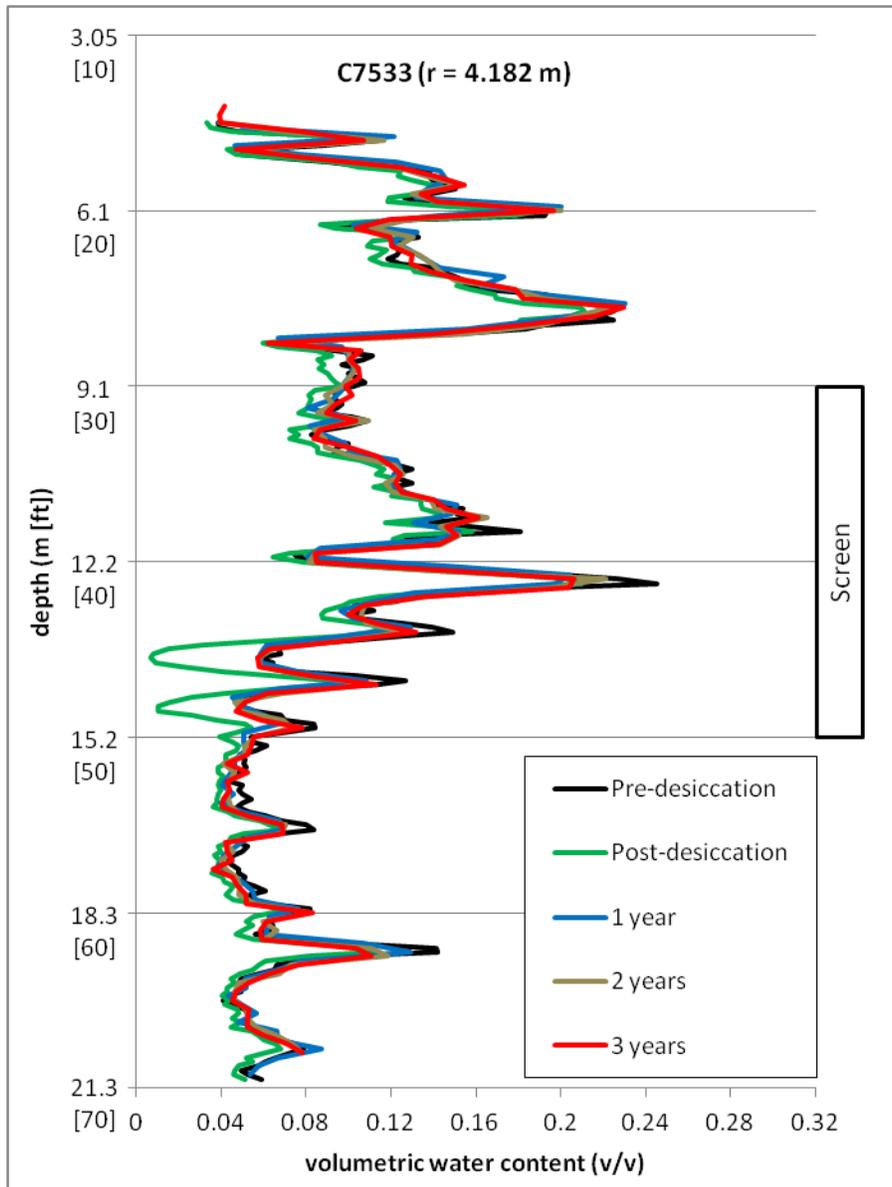

Figure 4.14. Neutron Moisture Probe Response over Time for Location C7533 (4.182 m from injection well). The pre-desiccation data are from a logging event in December 2010, prior to the continuous active desiccation period. Other data are for logging events after active desiccation ended.

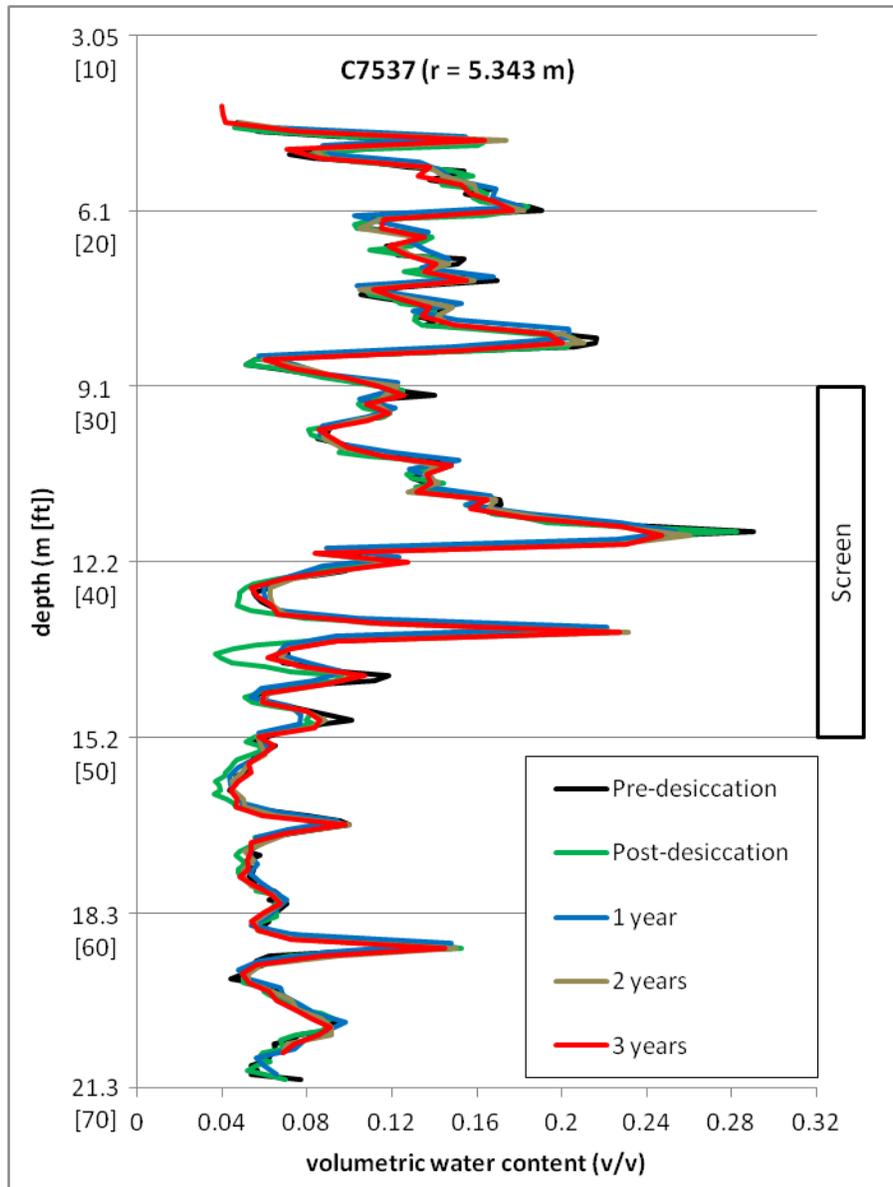

Figure 4.15. Neutron Moisture Probe Response over Time for Location C7537 (5.343 m from injection well). The pre-desiccation data are from a logging event in December 2010, prior to the continuous active desiccation period. Other data are for logging events after active desiccation ended.

4.1.1.3 Geophysical Data

Periodic GPR survey data were collected during post-desiccation monitoring. The GPR-interpreted volumetric moisture content distribution at day 137 during active desiccation and days 193, 265, 650, 770, and 980 after the end of active desiccation are shown in Figure 4.16. The GPR survey equipment malfunctioned during the survey event at day 1135 and these data are not usable for interpretation. Note that the GPR data at day 137, during desiccation, are prior to the end of active desiccation (e.g., day 164) such that conditions were likely dryer at the onset of the post-desiccation monitoring period. The post-

desiccation GPR data show a general increase in volumetric moisture content over time within the 2D survey cross section. In some areas, localized re-distribution of moisture has caused drying of some small zones as water moved to adjacent dryer zones. The GPR data indicate that the driest zones during desiccation near the injection well, including about 10 m bgs and about 15 m bgs, have remained the driest over time, although, within the resolution of the GPR analysis, they have increased in moisture content after the end of active desiccation. The GPR data show that the moisture content within these portions of the survey cross section is still dryer than pre-desiccation conditions (Figure 4.17).

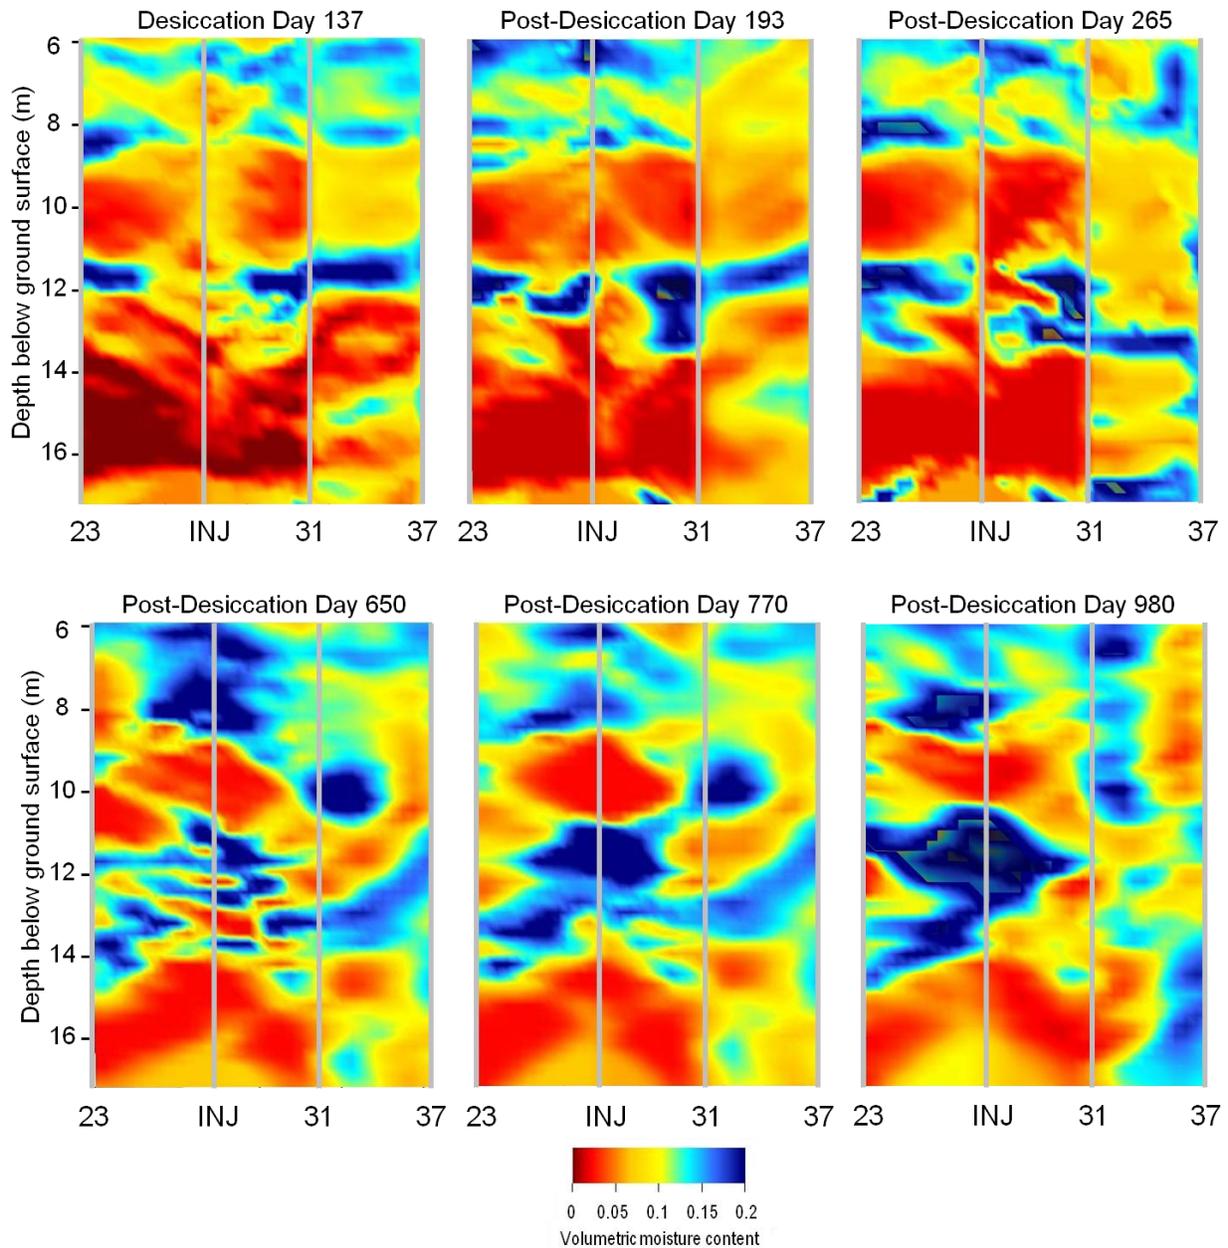

Figure 4.16. 2D Interpretation of Volumetric Moisture Content from Cross-Hole Ground Penetrating Radar Data during Desiccation (left) at Day 137 (June 3, 2011) and after the End of Active Desiccation. Locations are shown as INJ (injection well) and logging well locations are indicated by the last two numbers in the location identifier (e.g., 23 = C7523).

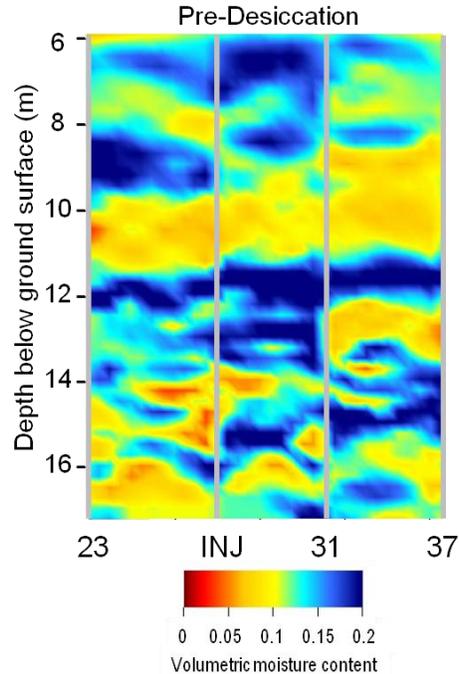

Figure 4.17. 2D Interpretation of Initial Volumetric Moisture Content from Cross-Hole Ground Penetrating Radar Data Prior to Desiccation. Locations are shown as INJ (injection well) and logging well locations are indicated by the last two numbers in the location identifier (e.g., 23 = C7523).

Interpretation of the 2D moisture content representation should consider that conversion of GPR-derived permittivity to volumetric moisture content (VMC) is affected by EC. Desiccation reduces the EC, which renders GPR data acquisition more favorable within desiccated zones, and improves the accuracy of the GPR-derived moisture content estimate. For example, Figure 4.18 shows the ERT-derived EC distribution along the GPR survey transect at the end of desiccation and at days 650, 770, and 980 post-desiccation. The black regions illustrate where low EC, or low-loss, assumptions may not be valid ($EC > 0.05$ S/m). Prior to desiccation, the low-loss assumption was generally valid above a depth of 10 m and invalid below 10 m. At the end of desiccation, low-conductivity conditions have been established within a zone from depths of approximately 13 m to 15 m (Figure 4.18). Within this depth interval, GPR-derived moisture content estimates correlated well with estimates from neutron moisture logging (Truex et al. 2012a). Within zones where desiccation has decreased the EC, GPR can be used with confidence to estimate the moisture content distribution between wells. At 650 days post-desiccation, low-loss conditions mostly remain within the 13-m to 15-m zone. However, by post-desiccation days 770 and 980, this zone appears to be recovering sufficiently such that low-loss conditions may no longer be applicable.

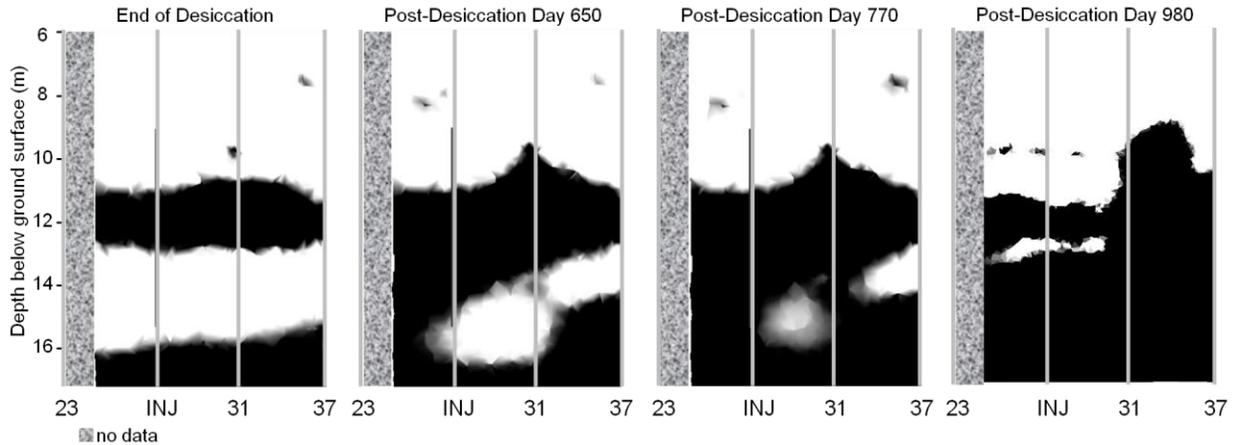

Figure 4.18. 2D image showing regions where GPR low-loss conditions (white) are valid, resulting in higher confidence in GPR-derived moisture content estimates. Locations are shown as INJ (injection well) and logging well locations are indicated by the last two numbers in the location identifier (e.g., 23 = C7523).

ERT monitoring was continued without interruption after active desiccation was terminated. Figure 4.19 shows the ERT interpretation of changes in the VMC expressed as the ratio of VMC at the time of the measurement to the VMC at the end of active desiccation (VMC_0). A ratio of 1 designates areas that have not changed from the conditions at the end of active desiccation. Ratios higher than 1 indicate rewetting; for instance, a ratio of 3 means that the volumetric moisture content is 3 times higher than it was at the end of active desiccation. Ratios lower than 1 indicate drying; for instance, a ratio of 0.75 means that the VMC is 0.75 times what it was at the end of active desiccation. The resolution of the ERT data inversion is on the order of a cubic meter. Thus, the ERT images cannot show sharp contrasts in wetting or drying zones over time, but show a “smoothed” image of how the subsurface is changing. As time progresses, some regions in the test area get wetter (proceeding from green to yellow to orange in color). The moisture for rewetting is being drawn from adjacent regions, as shown by areas that have become dryer (darker blue color).

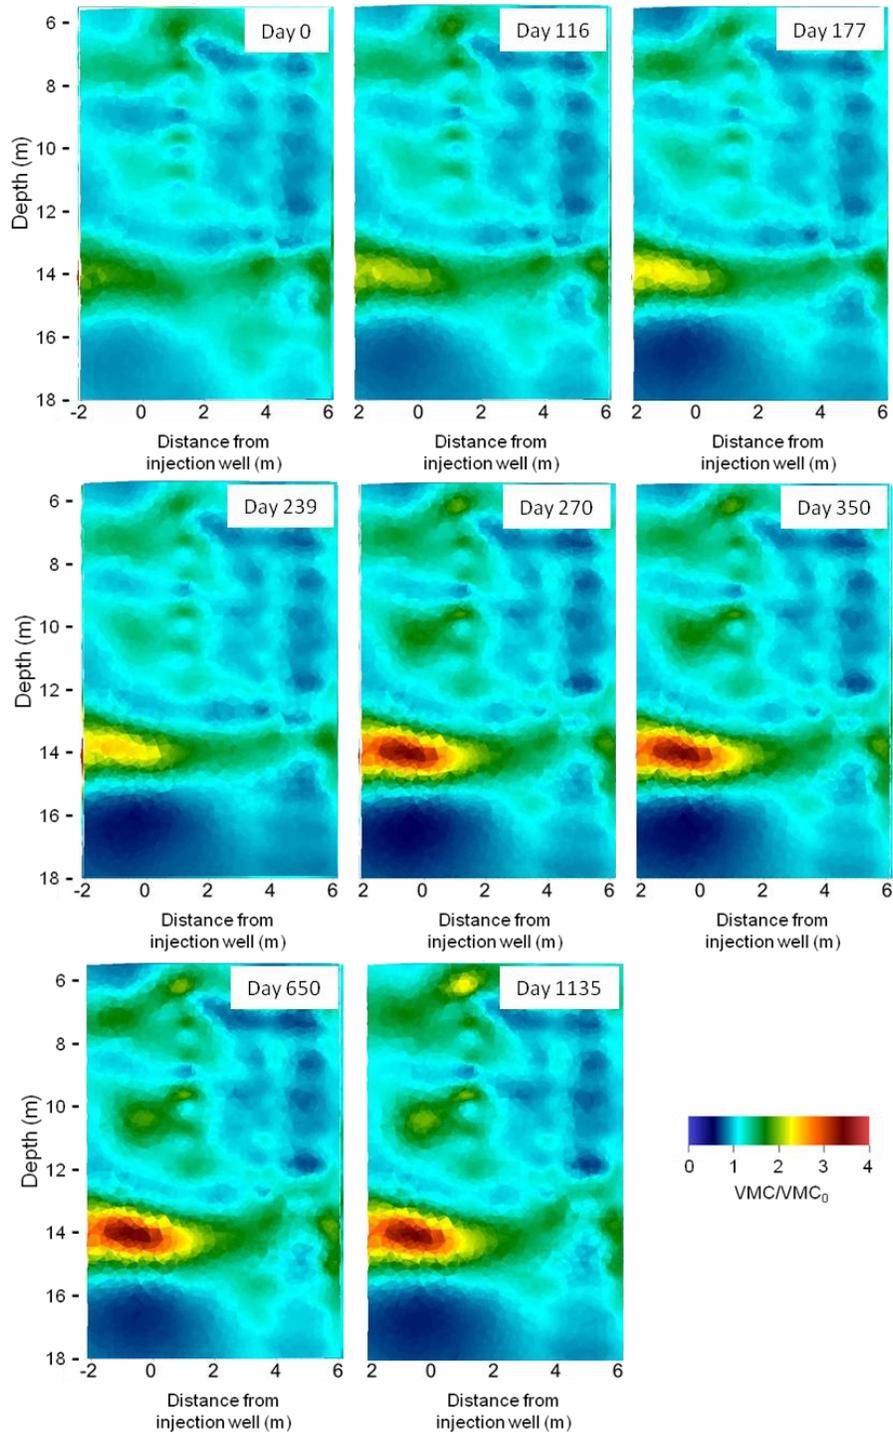

Figure 4.19. Ratio of Volumetric Moisture Content (VMC) to the Volumetric Moisture Content at the End of Active Desiccation (VMC_0) Over Time along the Axis between the Injection and Extraction Wells from Cross-Hole Electrical Resistivity Tomography. ERT data are from sensors at locations C7522–C7534 through day 1135 of the post-desiccation period (Figure 3.6).

4.2 Post-Desiccation Monitoring Data Assessment

Desiccation is intended to help meet remediation goals by slowing the movement of contaminated moisture through the vadose zone and thereby reducing the flux of contaminants into the groundwater. The rate at which moisture returns to the desiccated zone, here termed the rewetting rate, is important in the overall long-term performance of desiccation as part of a remedy.

Rewetting phenomena and rates have previously been studied through laboratory and modeling efforts. Laboratory data quantifying the rewetting process was collected and reported by Truex et al. (2011). Key conclusions were that vapor-phase rewetting can occur but the process only rewets the desiccated zone to a small extent, essentially to a level below the residual moisture content. Rewetting by aqueous transport occurs, consistent with standard hydraulic phenomena, such that desiccating to very low moisture content and creating very low aqueous phase hydraulic conductivity conditions leads to low rates of aqueous transport rewetting.

Previous modeling efforts (Truex et al. 2012a, 2013b) concluded that the rate of rewetting is a function of the porous media properties of both the desiccated zone and the subsurface surrounding this zone, as well as the moisture content distribution at the end of active desiccation. After active desiccation, the moisture content distribution in the target zone will trend back toward the equilibrium moisture conditions for the porous media properties. Vapor-phase rewetting will occur, but has a negligible impact on the overall rewetting process. Advective rewetting in the aqueous phase strongly depends on the porous media permeability within and surrounding the desiccated zone, the moisture content surrounding the desiccated zone, and the total thickness of the desiccated zone. For example, at the C7527 and C7529 monitoring locations closest to injection well, the thicker desiccated zones have shown the least rewetting. These thicker desiccated zones were areas of high injected air flow due to the presence of coarser, lower-moisture content sediments. While relatively wet sediments are present above these zones, the sediments below are also relatively coarse and dry. Therefore, rewetting of these zones has primarily occurred from above. Analysis of rewetting in this zone after two years of rewetting was presented in Truex et al. (2013b) and will be updated after additional data are collected in the future. This current report updates the rewetting data, but not the rewetting analysis.

Current data, 3-years after active desiccation was ended, show moisture redistribution in the subsurface at the test site associated with rewetting of desiccated areas. Areas that were moderately desiccated have largely returned to near pre-test conditions, though a redistribution of water from wetter to dryer zones is evident in many of the neutron logging results (Section 4.1.1.2). Rewetting is continuing for highly desiccated areas. However, neutron data from location C7529 still show a 1-m depth interval that retains very low moisture content. Qualitatively, trends of moisture redistribution over a broad zone in the vicinity of the test site are observed in the GPR and ERT data.

5.0 Conclusions

A field test of desiccation is being conducted at the Hanford Site 200-BC-1 Operable Unit. Desiccation technology relies on removal of water from a portion of the subsurface such that the resultant low moisture conditions inhibit downward movement of water and dissolved contaminants. A field test report (Truex et al. 2012a) describes the active desiccation portion of the test and initial post-desiccation monitoring data. An interim report (Truex et al. 2013b) was also issued to evaluate the first two years of rewetting data after active desiccation operations. An additional year's worth of monitoring data have been collected at the field test site during the post-desiccation period and are described herein. This is a second interim report, including about 3 years out of a total of 5 years of post-desiccation monitoring proscribed by the field test plan (DOE 2010b).

The treatability test is being conducted to provide information about desiccation that is intended for use in subsequent feasibility studies for waste sites with inorganic and radionuclide contaminants in the deep vadose zone. The active desiccation portion of the field test occurred over a duration of 164 days, ending on June 30, 2011 (Truex et al. 2012a). The injection and extraction wells were 12-m apart with multiple monitored locations surrounding the injection well. A clustered monitoring approach was used in the test whereby a "sensor borehole" containing sensors, gas-sampling ports, and electrical resistance tomography electrodes was placed nominally adjacent to a cased, unscreened "logging well" that was used to conduct neutron moisture logging and cross-hole GPR. Monitoring with the in situ sensors and geophysical techniques has been continued during the post-desiccation (rewetting) phase of the test.

Over time, the rate of moisture rewetting of the desiccated zones is a function of the hydraulic gradient, water relative permeability, and porous media unsaturated flow properties. Rewetting data since the end of active desiccation are consistent with expectations based on related laboratory data and numerical simulation analyses. Analysis of the data demonstrate that water advection from relatively wetter zones to dryer zones has occurred. For the zone of most extensive desiccation, nominally between 14 m and 16 m bgs, water advection has occurred primarily vertically downward from the wetter lower-permeability sediments at depths shallower than 14 m bgs. These shallower depth sediments were not significantly dried during desiccation operations. At many locations, a substantial portion of the water removed by desiccation has returned to the desiccation zone over the 3-year rewetting monitoring period. This relatively rapid rewetting was expected based on the moisture conditions within and adjacent to these locations. In the monitored zones showing the thickest vertical intervals of desiccation, rewetting increased moisture content in the shallow portion of the desiccated zone, but other portions remained dry. To date, the rewetting data are consistent with expectations for desiccation test performance based on laboratory and numerical simulations. These data are important to provide confidence in the design process to scale-up desiccation from the small test-site scale to a larger scale with sufficient capacity to maintain dry conditions over long periods of time and help mitigate contaminant flux to groundwater.

At the field test site, the injection well straddled low- and high-permeability sediments. Over the relatively short duration of active desiccation, the higher-permeability sediments were predominantly desiccated near the injection well. However, the moisture content of thick lower-permeability zones was not significantly reduced. Thus, for rewetting, the lower-permeability zones at the test site provide a source of water to rewet the desiccated zones. As described in the previous field test report (Truex et al. 2012a), full-scale desiccation as part of a remedy would seek to desiccate thick zones as part

of meeting performance goals. In addition, sequential application of desiccation and rewetting (inactive) periods can lead to a more robust desiccated zone by decreasing the moisture in lower-permeability zones where direct dry gas injection is difficult. However, at the test site, the presence of the moisture source in low-permeability zones adjacent to the desiccated zones has provided a condition where field-scale rewetting rates can be measured within the time frame of a treatability test and provide valuable confirmation of rewetting processes. With continued monitoring to evaluate the rewetting of the thicker desiccated zones at the site, a robust data set will be available to support evaluation of desiccation performance in support of future feasibility studies.

Neutron Moisture Probe Data

Appendix A

Neutron Moisture Probe Data

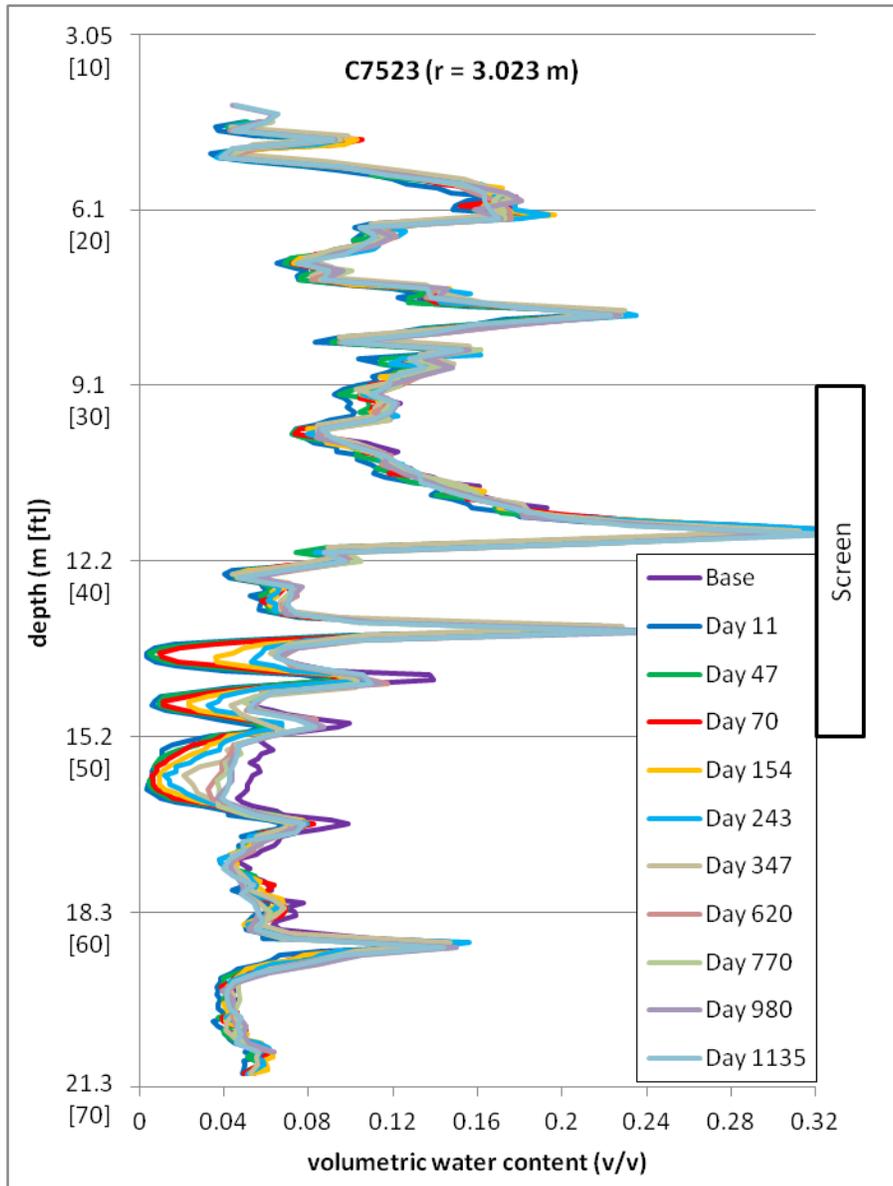

Figure A.1. Neutron Moisture Probe Response over Time for Location C7523 (3.023 m from injection well). The pre-desiccation data (Base) are for a logging event in December 2010, prior to the continuous active desiccation period. Other data are for logging events after active desiccation ended.

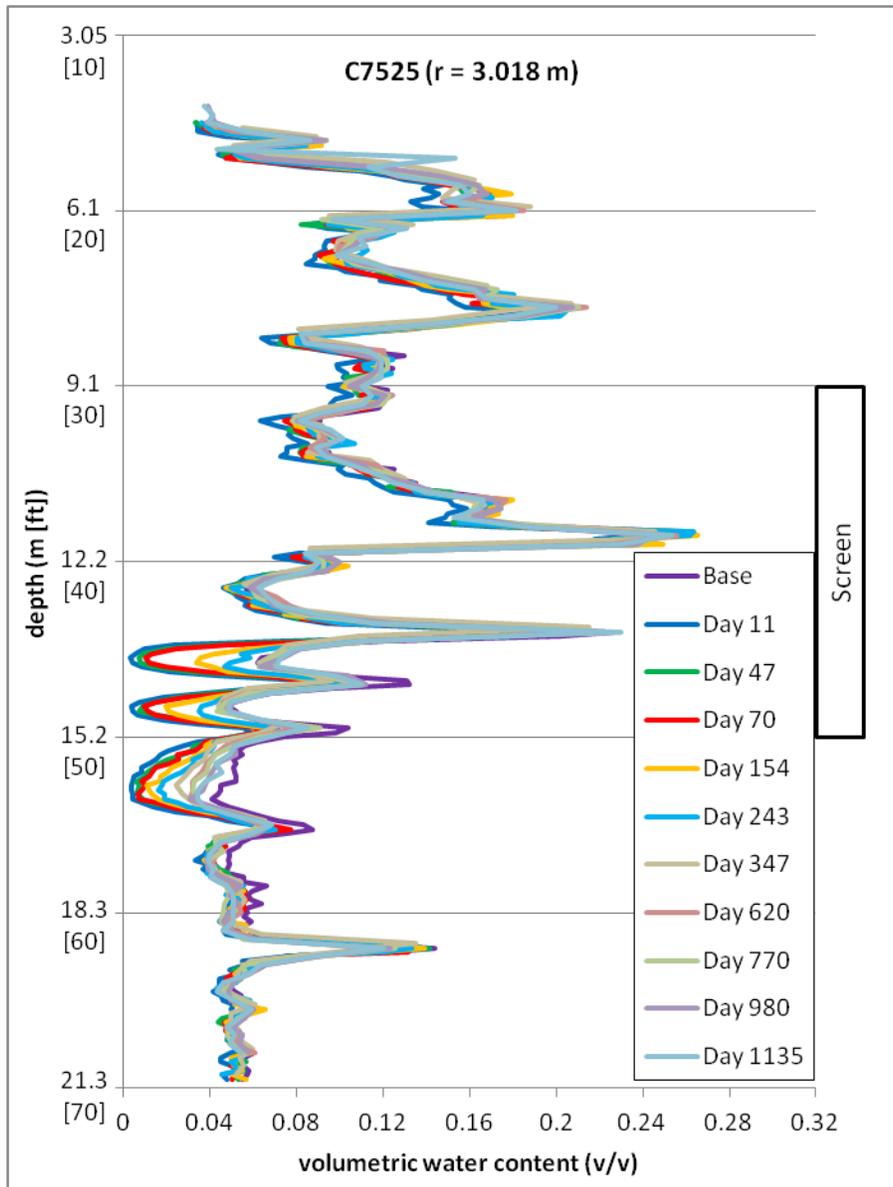

Figure A.2. Neutron Moisture Probe Response over Time for Location C7525 (3.018 m from injection well). The pre-desiccation data (Base) are for a logging event in December 2010, prior to the continuous active desiccation period. Other data are for logging events after active desiccation ended.

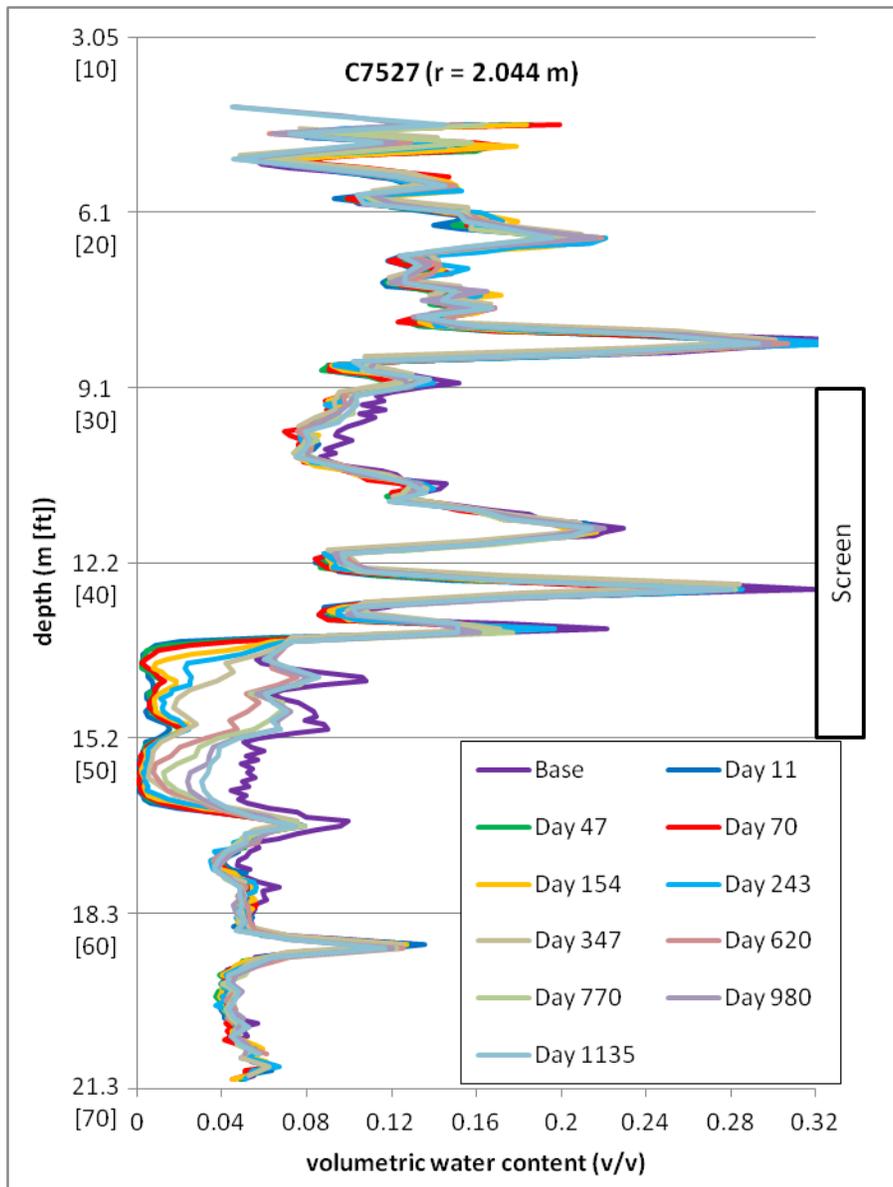

Figure A.3. Neutron Moisture Probe Response over Time for Location C7527 (2.044 m from injection well). The pre-desiccation data (Base) are for a logging event in December 2010, prior to the continuous active desiccation period. Other data are for logging events after active desiccation ended.

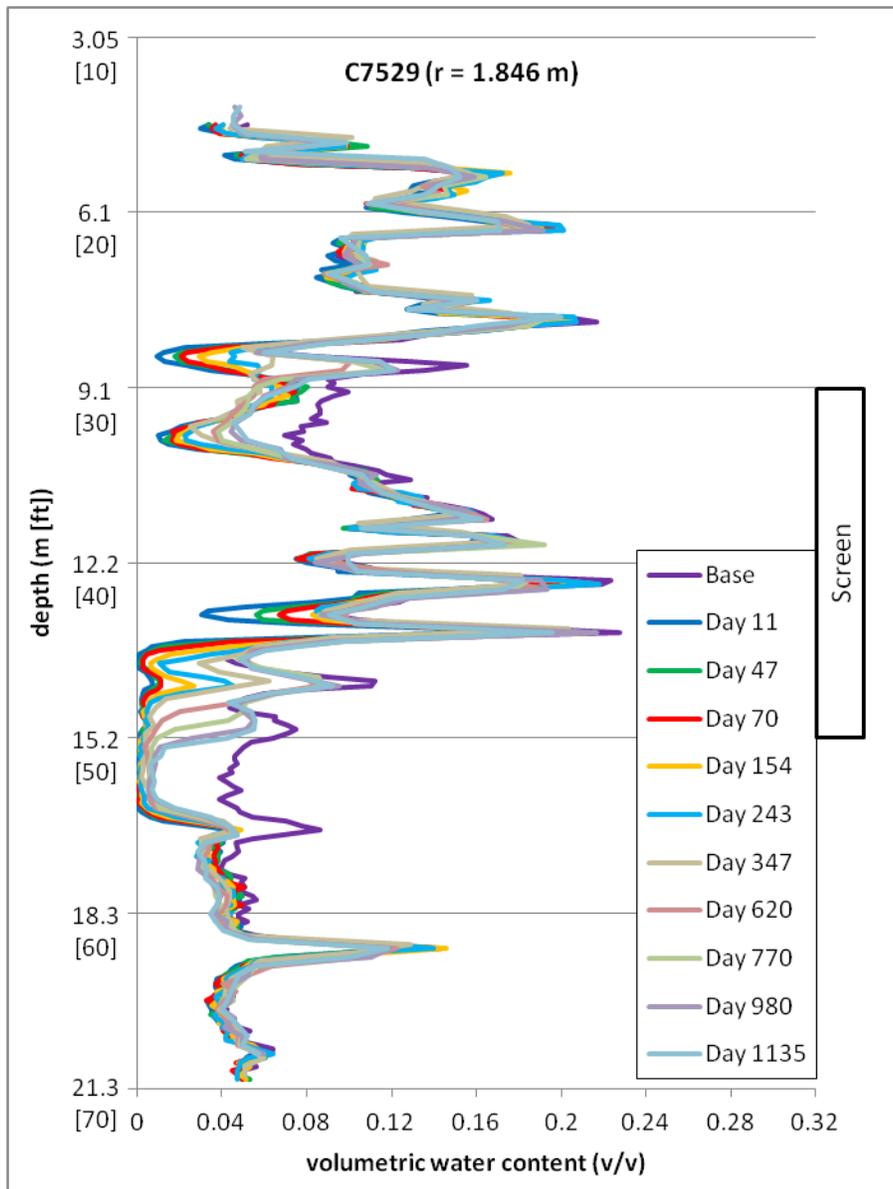

Figure A.4. Neutron Moisture Probe Response over Time for Location C7529 (1.846 m from injection well). The pre-desiccation data (Base) are for a logging event in December 2010, prior to the continuous active desiccation period. Other data are for logging events after active desiccation ended.

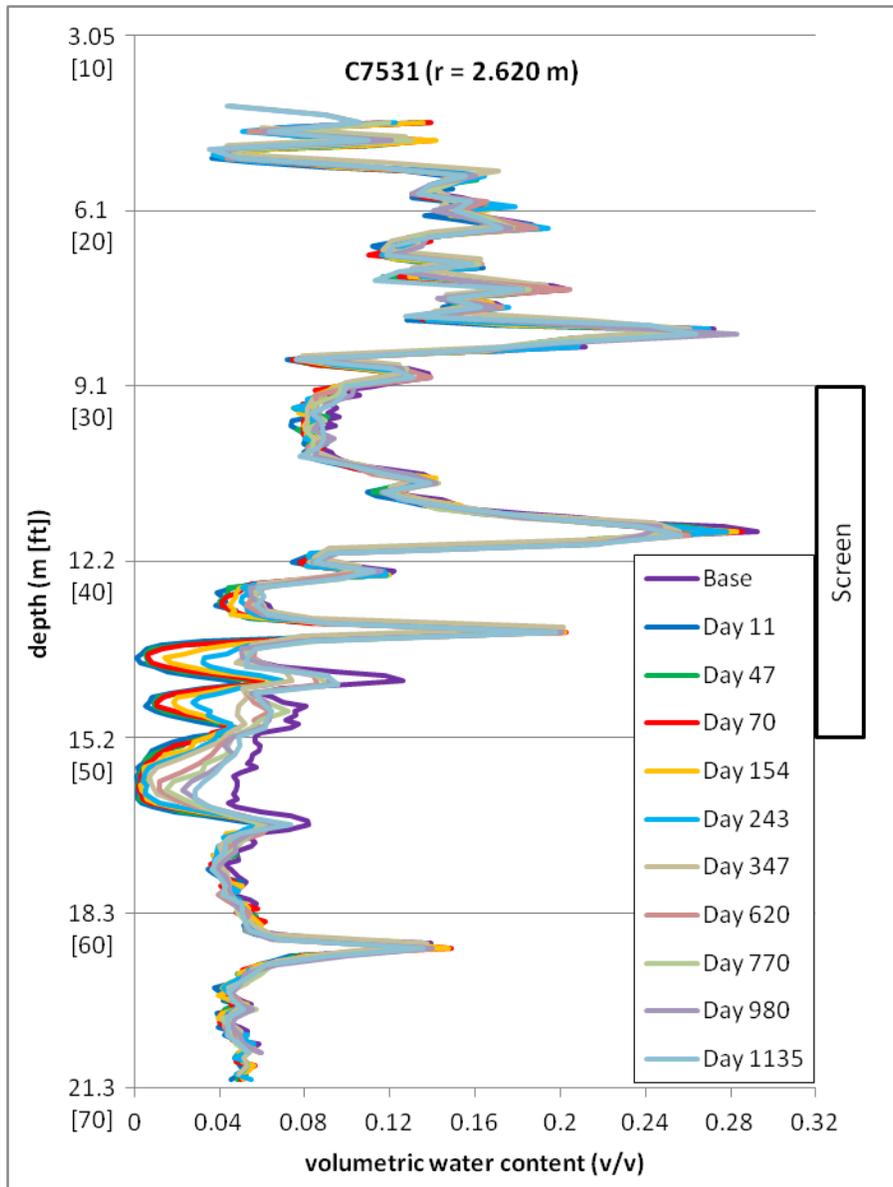

Figure A.5. Neutron Moisture Probe Response over Time for Location C7531 (2.620 m from injection well). The pre-desiccation data (Base) are for a logging event in December 2010, prior to the continuous active desiccation period. Other data are for logging events after active desiccation ended.

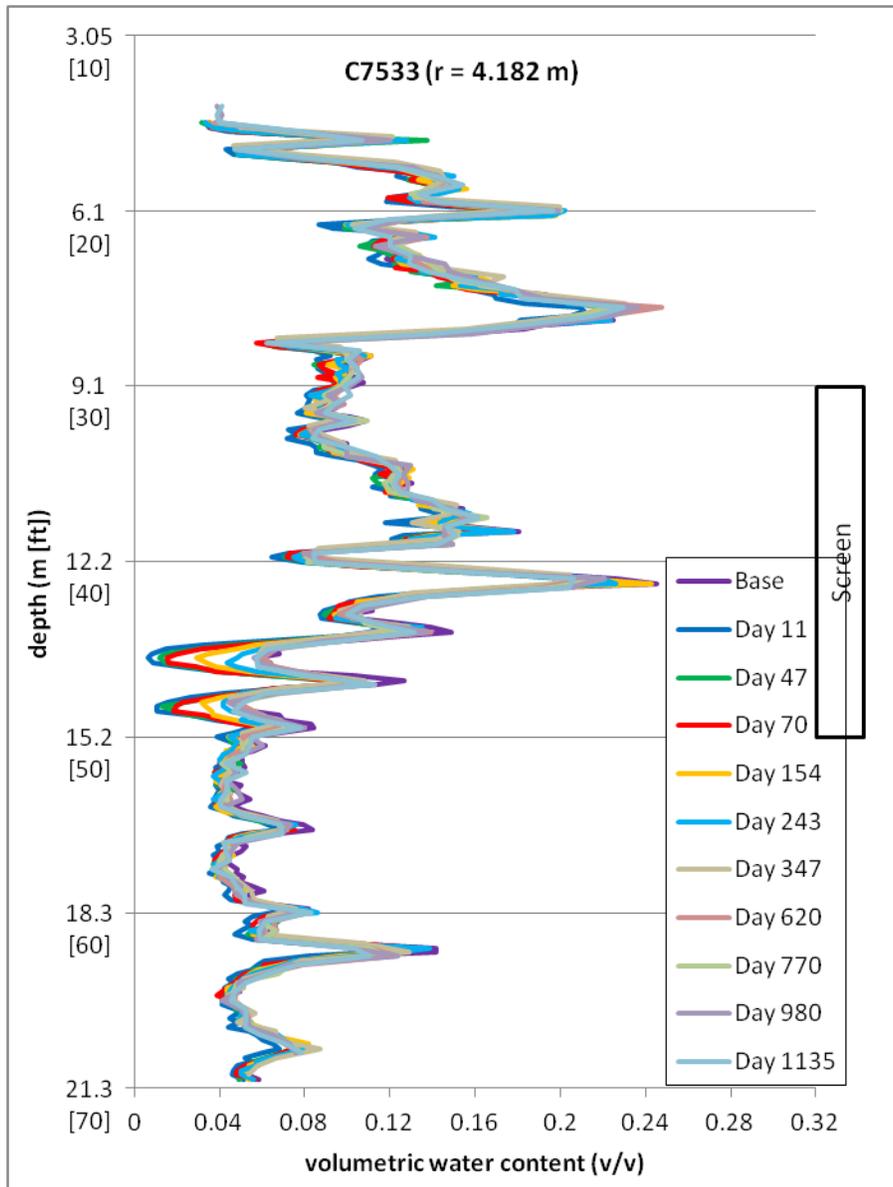

Figure A.6. Neutron Moisture Probe Response over Time for Location C7533 (4.182 m from injection well). The pre-desiccation data (Base) are for a logging event in December 2010, prior to the continuous active desiccation period. Other data are for logging events after active desiccation ended.

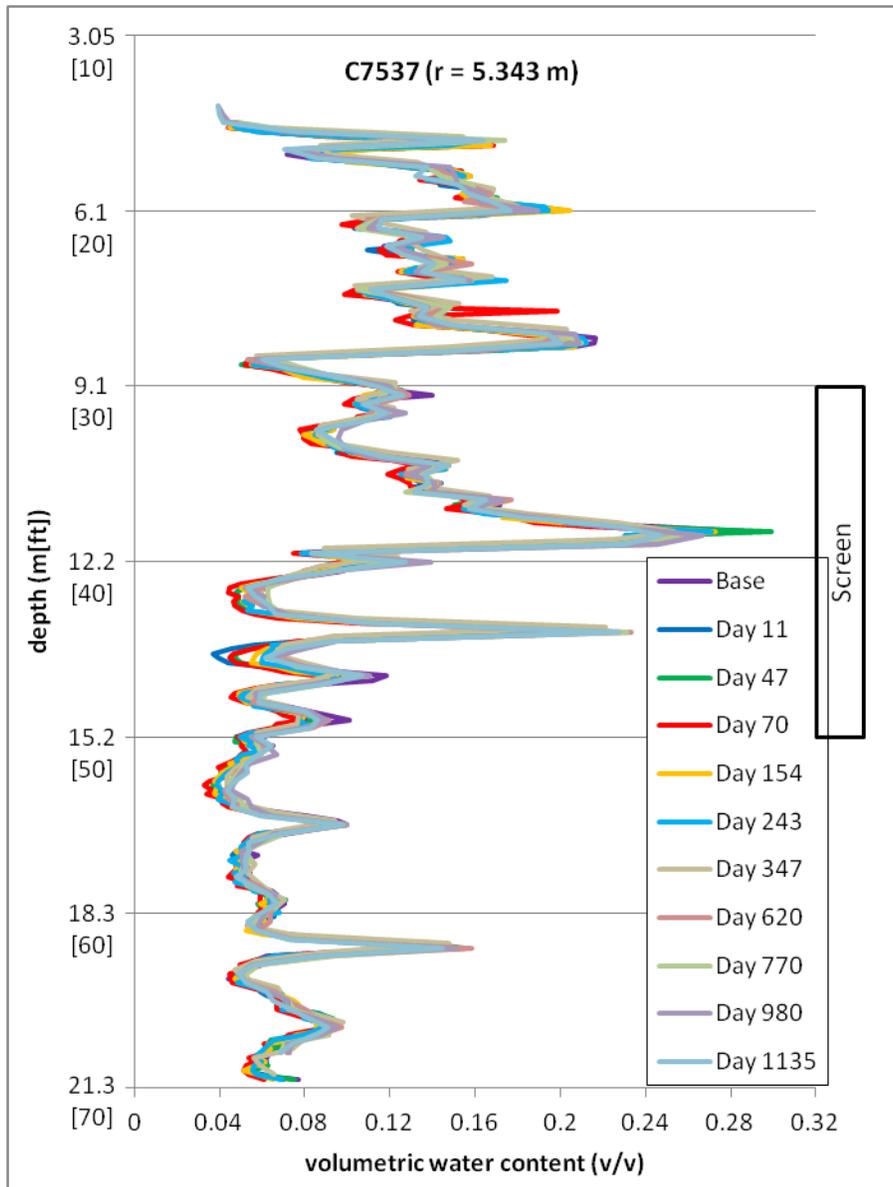

Figure A.7. Neutron Moisture Probe Response over Time for Location C7537 (5.343 m from injection well). The pre-desiccation data (Base) are for a logging event in December 2010, prior to the continuous active desiccation period. Other data are for logging events after active desiccation ended.
